According to the WTO, the top ten exporters of agricultural products and food in 2011 were (in decreasing order of percentage of world trade): the European Union (39%, 2011), the United States (9.7%, 2011), Brazil (5.7%, 2011), China (4%, 2011), Argentina (3.3%, 2011), Canada (3.2%, 2011), Indonesia (2.4%, 2011), Malaysia (2.3%, 2011), and Thailand (2.3%, 2011). The top three leaders' food trade earnings were US$520.4 billion, US$131.3 billion, and US$77.4 billion, respectively. The countries with the lowest overall trade in agricultural products in the top ten, still earned US$31.6 billion, US$44.2 billion, and US$31.7 billion in food trade, respectively (International Trade Statistics Section, 2012). Many of these countries trade the majority of their food products regionally. Europe, in 2005 and 2011 sold 81.2% and 78.1% of its food products elsewhere in Europe. North America, composed of Canada and the United States, sold 47.1% and 41% of its food goods within North America in 2005 and 2011. Asian countries revealed a similar trend, selling most of their goods to other Asian countries during the same years (55.7% and 56.4%, respectively). Interestingly, many of the leading agricultural exporters are also significant food importers from other leading exporters. The European Union's 2011 food imports accounts for 38.2% of the world's foods imports, followed by the United States (7.9%, 2011). Japan and China have the next highest share in imports with each importing 5.5% and 5.2% of the world food in 2011 (International Trade Statistics Section, 2012).

Although many countries were not leaders in world food importation, the food that they did import accounted for a large share of all their economies merchandise imports in comparison to these import and export leaders. For example, the European Union imported 38.2% of the world's food with a total value of US$549 billion, but it only accounted for 8.8% of their European Union's merchandise imports in 2011. Yemen's food imports accounted for 42.6% of all imports at a value of US$3.6 billion. Côte d'Ivoire's food imports have a total value of US$1.7 billion and account for 25.1% of their total imports. Syria, Senegal, and Sudan's food imports account for 21.1%, 22.9%, and 23.1% of total imports at a value of US$3.5, $1.4, and US$2.1 billion, respectively. Of course, there are other countries whose food imports account for greater than 20% of their total merchandise imports, but the value exceeds US$10 billion. Egypt's food imports in 2011 accounted for 23% of all imports at a value of US$13.6 billion, and Algeria's imports accounted for 22.6% of all imports at a value of US$10.7 billion. Clearly, the percentage of the total imports has very little correlation to the overall value in comparison to other countries (International Trade Statistics Section, 2012).

The Food Chain in the United States

Overview

The majority of the US food supply comes from domestic sources, but as the food supply system matured and Americans demanded more variety and convenience from their food products, imports also grew. The demand for a variety of fruits affected by the seasonality of the growing seasons and an increasing demand for nutritious foodstuffs also define the US's import markets. Every year, American farmers produce approximately US$143 billion in crops and US$153 billion in livestock (Massey, 2013). Less than 2% of the labor force consists of farmers. Farmers contribute approximately 1% to the gross domestic product (GDP) directly. This 1% translates into US$200 billion and is primarily concentrated in the

Midwest, California, and the East coast. Yet, greater than 16% of the labor force is involved in the food sector overall, and the industry as a whole makes up 11% of the national GDP. Despite the limited number of farmers in the United States, the average US citizen only spends approximately 11% of their income on foodstuffs. The global average is double that number at 20–30%. This is due to the highly advanced and productive nature of the US food supply (Monke, 2004).

Delineating the Protein Food Supply Chain

The animal protein sector of the US market will be used to describe the complexity of the food supply chain. Groups such as Cargill, Cenex, and multinational organizations have been discussed above. Animal protein production business in the United States has become highly integrated and this is especially true in the livestock sector. Livestock farmers are of a larger scale than ever before; they also generally raise a single species in enclosed housing. Further, beef cattle, hog, and poultry farmers often only raise certain age groups of animals. One farmer raises young animals, and adults are 'finished' by another farmer. Much of this highly industrialized system developed to allow greater value to the end product and to increase efficiency by the farmer.

The value of these animals and the payment received by farmers today is no longer driven by a daily, weekly, or monthly market system, but is instead based on services provided and contractual agreements. Livestock systems have geographic niches throughout the United States. Beef cattle feedlots are primarily found in Northern Texas, Kansas, Nebraska, Eastern Colorado, and Iowa. The leading dairy states are California, Wisconsin, Idaho, New York, and Pennsylvania. Hogs are found in Iowa, Minnesota, and North Carolina (Hoskin, 2012). Broilers are most predominant in Georgia, Arkansan, and the Delmarva Peninsula (Delaware, Maryland, and Virginia) (MacDonald, 2008). According to the 2007 US Census of Agriculture, there were approximately 96 million cattle and calves, 68 million hogs, 350 million layer birds, and 9 billion broiler birds in the United States in 2007 (National Agricultural Statistics Service, 2009). To highlight the complexity of the agricultural industry, the beef supply system and value chain will be discussed in detail and brief overviews of the pork, dairy, and poultry industries will be given.

Most of the livestock industry in the United States is segregated by production groups, often based on age and maturity of the animal. Beef cattle originate from cow–calf operations, often on ranges and pasturelands. When the animals are weaned, they are sold to finishing operations at feedlots (National Animal Health Monitoring System, 2011). The assurance in the supply of the calves has to be worthwhile to the feeder, finisher, or processor who is buying the calves in order to lock in an agreed-upon price. Small-scale farmers likely have a lesser ability in meeting the demands of these contracts. The result is that larger-scale farms are more vertically integrated, that is the producers sell to the same buyers in the production chain year after year. This is likely due to the use of contracts and on sales based on market value chain characteristics (National Animal Health Monitoring System, 2011). In the United States, the 10 largest feedlot operations account for 30% of the beef feeding capacity as well. Further, 10.5% of the industry are owned by the JBS Five Rivers and Cargill corporations. The move toward corporation and multiple owners versus single owner feedlot systems represents the benefits gained out of the economy of scale (Galyean, 2010). Feedlots can range in size from a few hundred head of cattle to thousands of head of cattle (Harvey, 2012; **Figure 2**).

Dairy production has increased dramatically since 1970. Milk production per cow has doubled whereas farm numbers have decreased a little over seven-fold from 650 000 farms in 1970 to 90 000 farms in the 2000s. Despite the number of farms being much smaller the average herd size has also grown five-fold, from 20 head of cattle to 100 head of cattle. Of all the milk produced, one-third is used for fluid milk sales. The rest is processed into other dairy products such as cheese, butter, yoghurt, ice cream, and so on. Almost half of the milk produced is made into cheese, with mozzarella being the most popular cheese type in the United States. In fact, the largest demand, and the major economic force behind the US milk industry is the demand for cheese. Its demand has doubled in the past 25 years, whereas fluid milk demand has declined slightly (Hoskin, 2012; **Figure 3**).

The pork industry in the United States has changed dramatically in the past 20 years, but the United States continues to be a leader in pork production with total pork sales numbering US$18.1 billion in 2007. Between 1992 and 2004, the number of farms involved in pork production dropped by 70%. Nonetheless, similar to beef, the number of swine in the United States remained stable at 60 million head of swine. Farms went from owning 945 swine on average in 1992 to 4646 swine in 2004, with more than 50% of the farms owning >5000 head of swine in 2004 (Key and McBride, 2007; Environmental Protection Agency, 2012; **Figure 4**).

The US swine industry is broken into two parts, but there are many phases to the actual pork production cycle. Breeding occurs shortly after a sow's piglets are weaned. Sows give birth almost precisely at 3 months, 3 weeks, and 3 days after breeding (113–116 days) (Environmental Protection Agency, 2012; Key and McBride, 2007). Many sows farrow or give birth to 3–5 litters in their lifetime and each litter is approximately made up of 8–12 piglets. When piglets are between 6 and 10 weeks the pigs move into a grower/finisher phase. The grower/finisher phase of production is the stage where the pigs are fed free choice until they reach market weight, which is approximately 250–275 lb (Environmental Protection Agency, 2012). Most phases are split into two- or three-tiers of production. Breeding and gestation often occurs at one location whereas farrowing, nursery, and growing/finishing are done at another location (Environmental Protection Agency, 2012). These production phases are either done through one business or through separate businesses focused on phase of production (Key and McBride, 2007), farrowing, and nursery age pigs are often raised in one location and then transported to a grower/finisher farm. The leading hog producing states in the United States are Iowa, North Carolina, Minnesota, Illinois, and Indiana (Pork Checkoff, 2012).

Poultry production has changed dramatically since the early twentieth century when a large number of households owned at least a few chickens. Today, the industry comprises farms that focus on one area of production for one species.

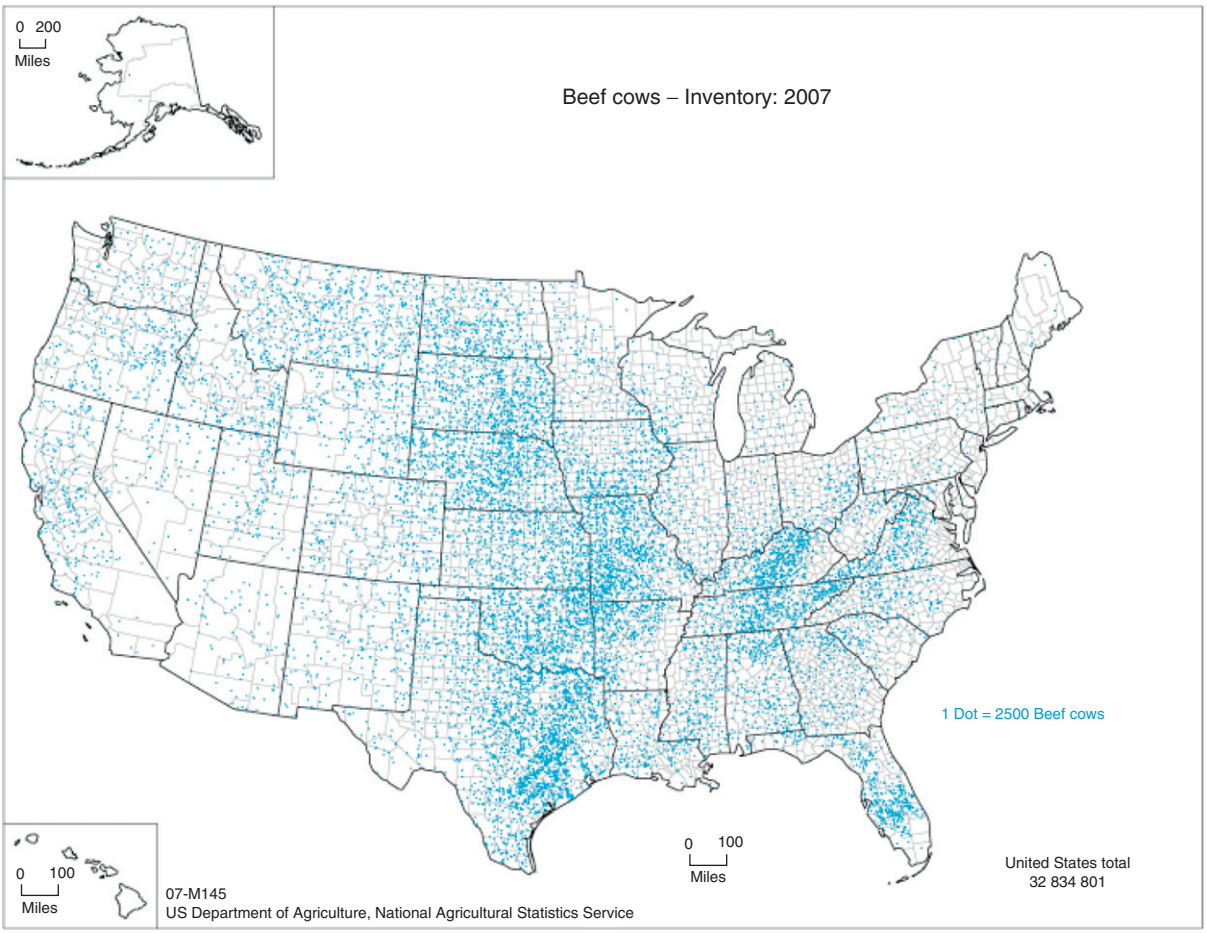

Figure 2 Beef cattle distribution in the United States, 2007. Reproduced from United States Department of Agriculture.

Birds are raised as layers (eggs) or broilers. Farmers may also be pullet producers (young chickens) that are supplied to broiler and layer production farms. (MacDonald, 2008; Harvey, 2012). In total, approximately 18% of poultry products are exported from the United States and it is the leading global poultry producer, as well as the second leading egg producer and poultry product exported (Harvey, 2012).

The majority of the poultry production is found in the broiler production industry. Broilers are young birds raised for meat (Economic Research Service, 2009a,b). The majority of farms are found in the area spanning Delaware to Georgia on the Eastern Seaboard and extending as far West as Oklahoma and Texas. The leading poultry producing states are Georgia, Arkansas, Mississippi, and North Carolina, in order of decreasing production. Production is coordinated differently than other animal production systems. The growers supply all the needs and labor for growing the birds from pullets to market weight birds, which takes approximately 6–8 weeks. A group known as 'integrators' manages the pullets, feed, and processing industries and contracts with the growers to prepare the birds for slaughter and therefore market (MacDonald, 2008). They, therefore, supply the pullets (young birds), veterinary care, and feed for the birds. The processors essentially contract out the cost of growing the birds (**Figure 5**).

The egg industry is markedly different from the broiler industry in that it is vertically integrated, meaning that one company owns the birds, manages the eggs, and sells the eggs. Yet, typically, the layer stock is still purchased from another company, with chicks arriving at the laying farm from the hatchery within 1 or 2 days after hatching. At the laying farm they are either placed in a laying cage or raised in a pullet house where they are fed until they reach approximately 3 pounds (1.4 kg) in weight, which takes approximately 15 more weeks. Between 15 and 18 weeks of age the hens are moved to the laying barn where daylight length is increased and feed becomes *ad libitum* or always available as layer hens regulate the food intake. The daylight exposure assists in initiating the onset of egg laying. At 60–70 week approximately 50% of the birds are laying, which is typically seen as the economic breakeven point for the producer. At this point, farmers will induce a molt in the birds, to increase the egg-laying life of the majority of the birds in the flock to approximately 100–110 weeks of age. At this point, between 100 and 130 weeks of age, most hens are sent to a spent hen facility where they are processed for meat production into items such as pet food, canned chicken, chicken soup, etc. or for disposal. The molting process is critical to farming efficiency and deserves more explanation. Molting is the process where hens lose their old feathers and grow back new ones. It is a

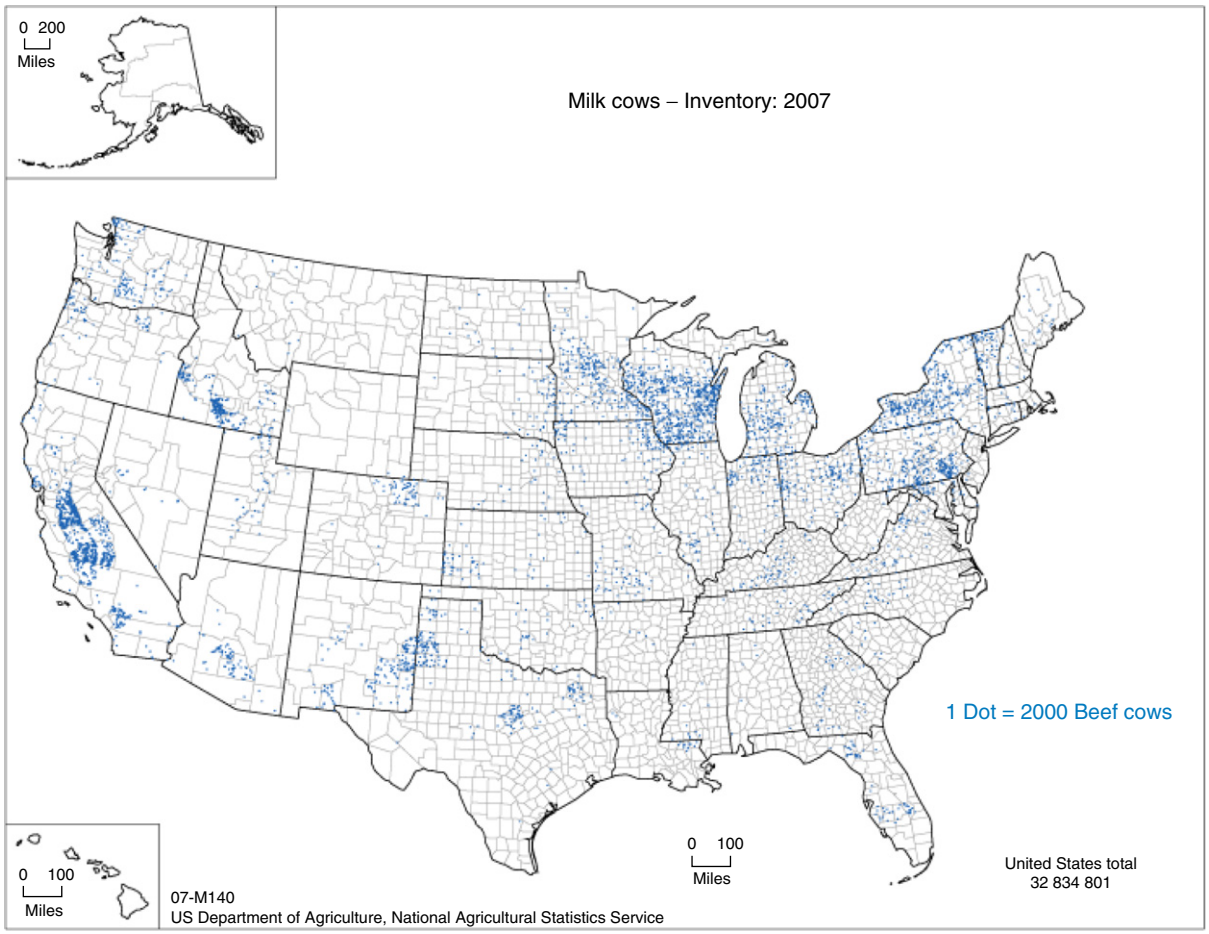

Figure 3 Dairy cow distribution in the United States, 2007. Reproduced from United States Department of Agriculture.

hormonal process coupled with light manipulation (Carey and Brake, 2007).

Social Values and Food in the United States

Developed countries have experienced a sharp decline in the number of farmers whereas the size of the farms has increased dramatically (Martinez, 2010). Although 70% of the poorest people in the world rely on animal agriculture for their survival (Zoonoses and Veterinary Public Health Department, 2006), developed nation populations are essentially disconnected from their food sources. They contact the end products but never interact with the crops or animals that provide the nutrition. Their food products are already slaughtered, pasteurized, gathered, processed, and packaged before the consumer even considers them as a food product. The system is industrialized for economy of scale and the product flow occurs at regional, national, and global levels. This is true of the United States as well. Since the 1990s, the realization within the American public that national animal production standards were not in line with consumer values has resulted in the popularity of a number of movements. These include the 'Buy Local' movement, in support of smaller scale local farmers and a lesser reliance of fossil fuels to gain food availability (Martinez, 2010; ERS); organic foods, related to concerns about pesticides, the use of hormones, and other additives; and the cage-free and grass-fed poultry and beef management movements, which address animal welfare. For example, the number of local farmers markets almost doubled between 1998 (2756) and 2009 (5274) (Martinez, 2010).

The Food Chain in India

With a population now exceeding 1.21 billion people, the Republic of India faces a unique set of challenges in the production, supply, and distribution of food. Since gaining independence from the British in 1947, India has radically transformed farmers' agricultural practices in order to achieve greater food security, yet the flow of goods remains traditional in many respects. The rise of the middle class, increasing urbanization, and changes in food preferences are predicted to have significant impacts on the country's food chain in the years to come.

Background

India has a long and rich farming tradition, dating back to 9000 BC. The amount of arable land in India is second only to

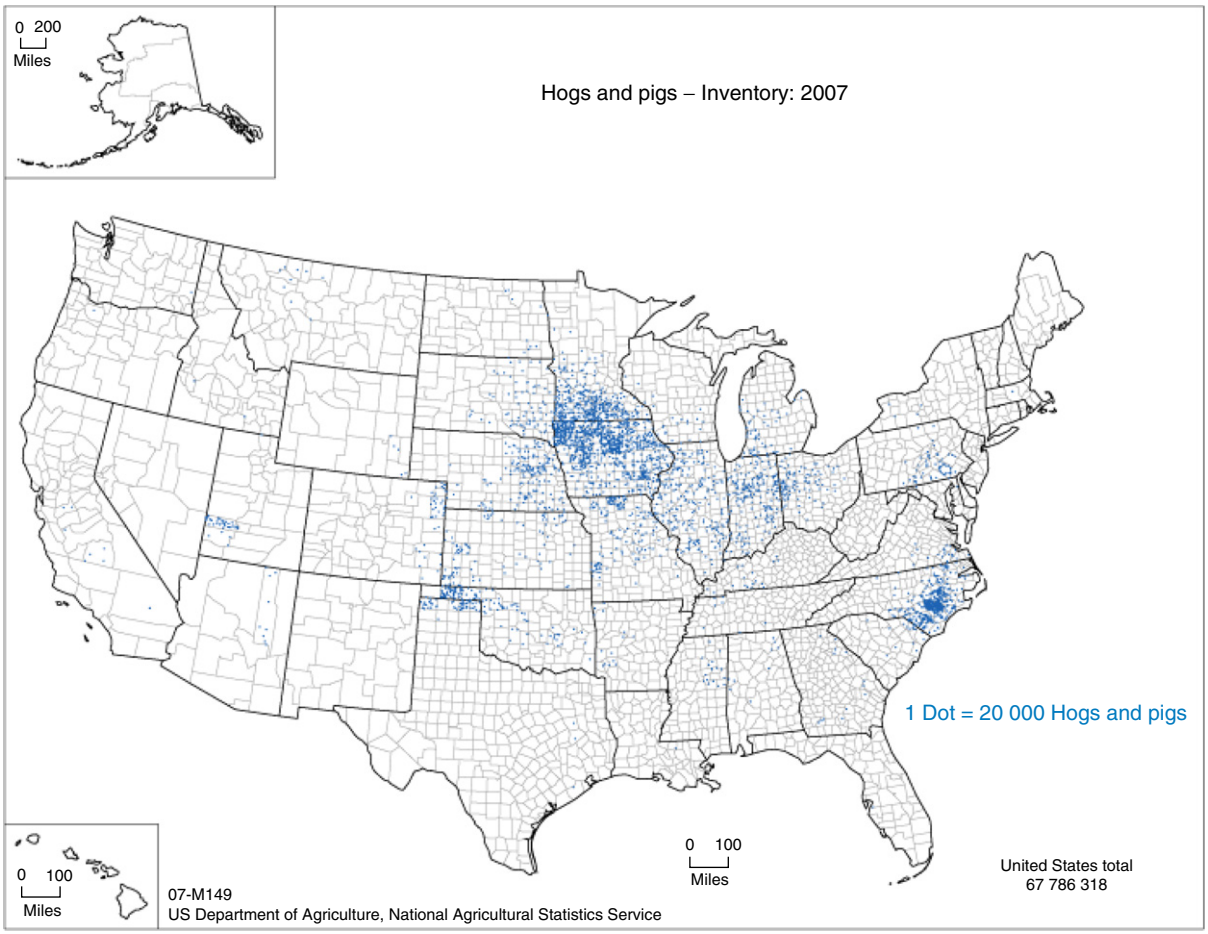

Figure 4 Swine distribution in the United States, 2007. Reproduced from United States Department of Agriculture.

the United States (Economic Research Service, 2012). Over time, the variance of soil and climatic conditions across the country has led to the geographic concentration of certain crops. For example, approximately 90% of the wheat currently grown in India is concentrated in the northern part of the country.

At the time of Independence, approximately 9 in 10 Indians were involved in some form of agriculture (Parvathi and Arulselvam, 2013). Yet food shortages plagued the country, as they had under colonial rule. The nascent Indian government pledged to support the most malnourished of its populace by guaranteeing a minimum supply of affordable grain. To meet this demand, India was forced to import as much as 10 million tons of food per year (Saha, 2013). In the 1950s, flooding and drought in the northern regions of the country exacerbated the existing food insecurity, and the people of India were threatened with widespead famine.

In 1967, the Indian government responded by instituting the technologies of the Green Revolution. As championed by the plant geneticist M.S. Swaminathan, the use of high-yielding seed varieties, accompanied by improvements in irrigation and the adoption of chemical fertilizers and pesticides, produced stellar advances in the country's food production. By the late 1970s, India boasted a record grain output of 131 million tons, and a food surplus was soon established. In the four decades after 1968, India's production of cereals more than doubled. The government targeted hunger reduction among its poor through heavy subsidies for wheat, rice, and sugar crops.

In the decades following the Green Revolution, the Indian government has demonstrated comparatively low levels of investment in agricultural research. According to the Center for Policy Alternatives in New Delhi, public investment in farming actually fell by one-third from 1980 to 2002. This trend has been accompanied by limited access to loans for farmers. As a result, there has not been any official (or unofficial) expansion of technologies to improve crop yield, and only approximately 40% of Indian farms are irrigated today. Since the mid-1990s, there have been 150 000 suicides among small farmers in India, with most of these attributed to financial strain. As a result of production challenges, the two primary sources of protein and calories in the Indian diet – lentils/peas (pulses) and vegetable oils – are increasingly being imported because farmers cannot meet the country's demand.

Structure of the Food Chain

Agricultural Produce Marketing Acts and Agricultural Produce Marketing Committees

In India, state governments are broadly responsible for the legislation and regulation of the agricultural sector, including

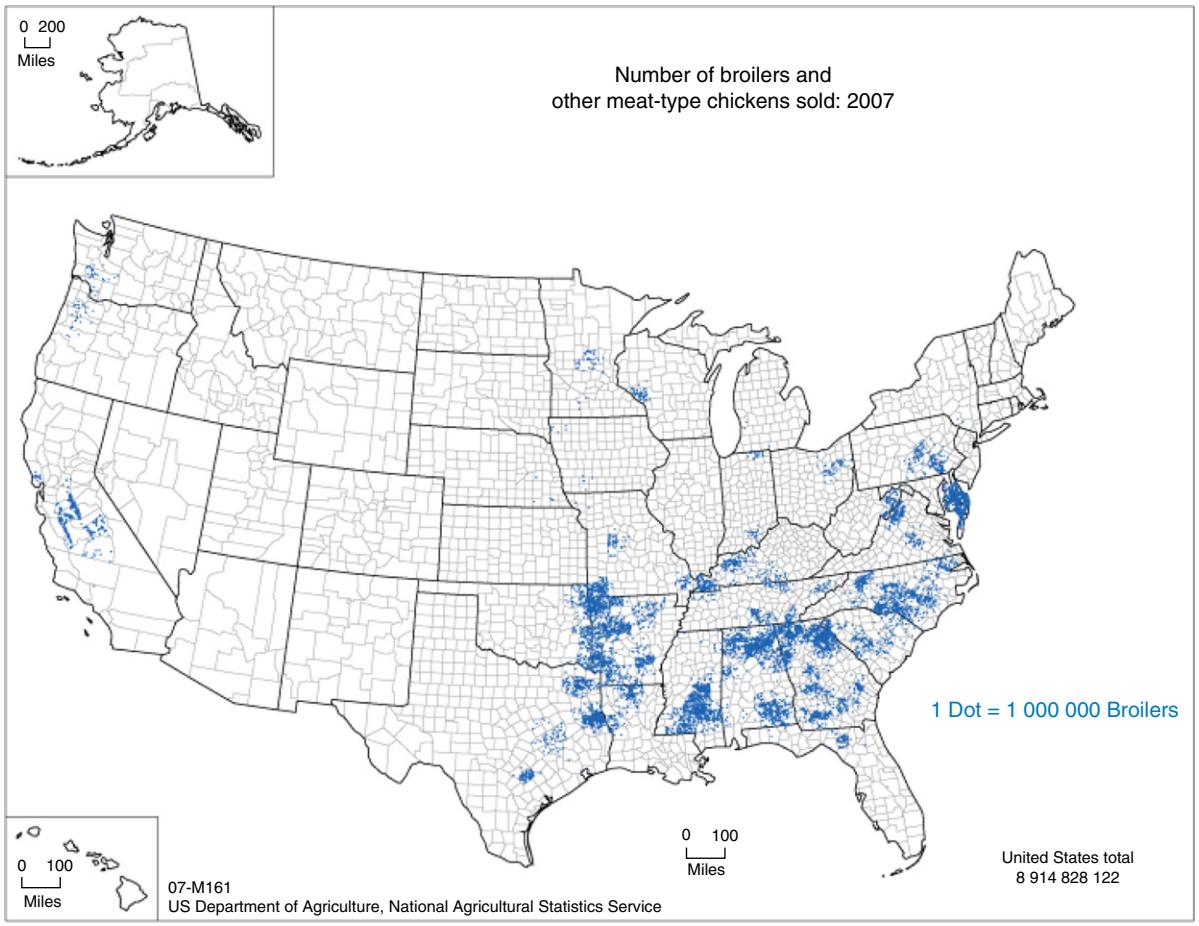

Figure 5 Poultry distribution in the United States, 2007. Reproduced from United States Department of Agriculture.

Farmer (unregulated) → Preharvest Contractor (unregulated) → Commission Agent/Broker (APMC regulated) → Wholesaler (APMC regulated) → Retailer (unregulated) → Consumer

Figure 6 The food supply chain in India. Reproduced from Gujral, J., Joshi, P., Anuradha, R.V., 2011. Facilitating Legislative and Administrative Reforms in Agricultural Marketing by Leveraging the Competition Commission of India. Canberra, Australia: Australian Centre for International Agricultural Research.

produce, livestock, and products of livestock. The Agricultural Produce Marketing Acts (APMAs) establish agricultural produce and marketing committees (APMCs) in each state to control the sale, storage, and marketing of produce. APMCs have approximately 12 members, who are either nominated by the state government or elected by the market areas.

Local market yards, called mandi, are established by the APMCs for the purposes of trade. Farmers typically sell their produce in these wholesale markets or through a broker (who charges a commission) and prices are set in an open auction. Retailers purchase produce through the APMC-regulated wholesalers and market them to the final consumers (Figure 6).

Critics of the existing trade system cite innate problems with efficiency, the accompanying lack of innovation in food storage and transport, and restrictive policies that limit farmers' ability to sell outside of the mandi (such as directly to private food retailers). The supply chain also includes overcrowded roads and a largely underdeveloped, unrefrigerated rail system. By some estimates, the average farmer receives less than a fifth of the price the consumer pays (Singh *et al.*, 2002).

Food Corporation of India and Targeted Public Distribution System

Although the legal responsibility for agricultural trade rests in the states, the federal government plays a powerful role in its heavy procurement of agricultural products for public distribution. In 1964, the Food Corporation of India (FCI) was established under the Food Corporation Act. The FCI is a parastatal agency with the following goals (Food Corporation of India, 2014):

- effective price support operations for safeguarding the interests of the farmers;

- distribution of food grains throughout the country for public distribution system; and
- maintaining satisfactory level of operational and buffer stocks of food grains to ensure National Food Security.

The FCI is organized on a regional basis and is closely associated with the local food supply chains described above; in fact, the FCI is mandated to buy exclusively through the mandi. Approximately half of India's grain market is funneled through the agency, which typically procures supplies from surplus areas and delivers them to deficit areas. This amounts to 22 million tons of grain over 1500 km, or 12 million bags of grain transported every month.

Before each crop season, the FCI establishes a minimum support price (MSP) for 24 major crops, including seven cereals (rice, wheat, barley, sorghum, pearl millet, finger millet, and corn), five pulses (chickpea, pigeon pea, mung bean, black lentil, and red lentil), eight oilseeds (peanut, canola, toria, soybean, sunflower seed, sesame, safflower seed, and niger seed), coconut, raw cotton, raw jute, and virginia flue-cured tobacco. These prices are calculated on the basis of recommendations from the Commission of Agricultural Costs and Prices and are intended to reflect the costs of various agricultural inputs. The MSP is also susceptible to the influence of economic and political factors, and could potentially be used to incentivize farmers to plant certain crops over others.

In 1997, the FCI began using the Targeted Public Distribution System (TPDS) (replacing the Universal Public Distribution System) to deliver food to its citizens in need of assistance. TPDS establishes two categories of need (families below and above poverty line), and distributes a limited amount of grain to these families at subsidized rates. Critics of this system claim that not enough families have been identified and that the allotment of grain is insufficient to meet their dietary needs. There has also been a perceived 'leakage' of the national grain supply – a mismatch between procurement and distribution due to poor transport, inadequate storage, and failures in marketing.

Future Trends

Personal wealth and urbanization

According to the United Nations, India is predicted to have a population of 1.42 billion by 2026. In recent years, the country has been characterized by rapid economic development – rises in both GDP and average individual income. Furthermore, as in many developing countries, India's urban population has increased at the same time as its middle class has swollen. Over the past four decades, the urban population within the country has expanded from 17% to 30% (Sup Lee, 2012). City dwellers also generally have more disposable income for food purchases. As a result, urban food markets face much higher consumer demands than those in rural areas.

The food chain in India is being significantly altered by social changes as well. Women are increasingly present in the workplace, which means they have less time at home for food preparation. Lifestyles are becoming more fast paced, particularly in urban areas. Thus, the wealthiest consumers are spending more of their food budget (58%) on highly processed foods because of the convenience factor (Minten *et al.*, 2009). There is also more widespread access among the general population to modern, food-related technology such as microwaves and refrigerators.

Shifts in food preferences

Changes in India's demography have been accompanied by significant shifts in food preferences. Many consumers are substituting higher-value fruits, vegetables, and protein such as fish, meat, and dairy for the traditional grains and pulses. For example, cereals accounted for a much smaller percentage of total food expenditures in 2007 – only 24% in the urban population and 32% in the rural population (as compared with 34% and 56%, respectively, in 1972) (Minten *et al.*, 2009). In 2009 alone, spending on fruits and vegetables increased by nearly 9% as compared with the previous year. Meat, eggs, and fish were purchased at an increase of approximately 30%, whereas spending on cereals was unaltered (Winterbottom and Jadhav, 2011).

In addition to nutrition and health, many consumers in India are becoming more concerned with food safety and quality. The Food Safety and Standards Authority of India (FSSAI) enforces national laws and regulations pertaining to the production and retail of food supplies, although many producers have also instituted internal food safety management systems.

In general, there is a growing demand for variety in food products, with modern consumers preferring several choices over a single brand. In India, and throughout Asia, the retail food market is rapidly being filled with packed and branded products. Even in poor areas, producers recognize that they can charge higher prices after establishing loyalty and a 'brand value' of quality and safety (Minten *et al.*, 2013). Illegal brands, which are designed to mimic those that are well known, are often associated with lower quality and safety. This phenomenon is symptomatic of the relatively minor enforcement of intellectual property rights throughout the country and elsewhere in the developing world.

Modernization of distribution networks

As discussed earlier in the Section Supermarket Revolution, India is part of the third wave of the 'Supermarket Revolution.' With only 4% of food markets surpassing 500 sq ft, the vast majority of retailers are still small and are family owned. However, a recent surge of larger food retail chains (such as Reliance Fresh and Namdhari Fresh) is predicted to bring improvements in supply chain management, including the use of more modern, temperature-controlled warehouses and transportation (Goyal, 2010). Reliance Fresh, which was created by Reliance Industries in 2006, grew from just 330 stores in 2007 to 1400 as of 2013. At approximately 4000 sq ft each, these stores are filled with fresh fruits and vegetables, dairy products, and assorted other groceries and household staples. Attracted by the rapidly growing economy, large foreign corporations such as Tesvo (UK), Carrefour (France), and Walmart (United States) will likely be entering the Indian market in the near future.

Many supermarkets contract their goods from local suppliers in addition to big distributors. Increasingly in India, fresh food retail chains are purchasing fruits and vegetables

directly from farmers rather than through the government-run mandi (wholesale markets). This arrangement has the potential to improve the livelihoods of small producers, as well as lower operational and storage costs for the private enterprises (Goyal, 2010). To promote these changes, the Indian government has made some significant reforms to agricultural marketing policy. In 2003, an amended Model APMC Act was circulated, which relaxes the regulations on farmer direct marketing and allows for the establishment of private markets and contract farming. It has since been implemented by 16 states.

Conclusion

The food chain has moved from subsistence to local production to a complicated, highly integrated global system that has created numerous challenges and benefits. The food chain has also become an industry, generating a food value chain along with the food supply chain. This global market and its value chain have yielded increased standards for trade reasons as well as social values. As a result the supply import/export supply chain has become dictated by economy of scale, capability to create certain levels of quality, and that is accessible to distribution chains. The result is that not all food producers are able to become integrated into the food chain. In addition, although in many places, food security has improved overall, food's availability is not evenly distributed, and accessibility is limited by income, creating nutrition, and hunger problems persist. The United States has developed a complicated food industry, and the protein industry was highlighted to show the compartmentalized nature of the industry. India is a country with an interface between traditional agriculture and modern industry. The challenges facing India are its geographic span, population size, and a centralized model of food distribution. The food chain is not a simple topic, and is different between each country in the world, and within each country of the world. Yet, the principles and challenges discussed here highlight some of the characteristics and the infrastructure of the food supply today.

Food Engineering

Definition

Even though the word engineering has come to us through many languages (Latin, French, and now English), it ultimately stems from classical Greek. It is a combination of *εν*(*ι*) – eni: in or into, and the verb *γείνομαι* (geinomae): to create, to engender, to bring into being. Engineering sciences are by definition synthesizing sciences: they aim at conceptually creating a product or process, and within this activity, being a science, they strive to obtain insight into nature. This synthesizing nature is in contrast to the more analytically oriented disciplines, such as chemistry, physics, or biology, which just aim to understand specific aspects of nature. The engineering sciences employ and combine parts of these disciplines into the creation of products and processes. The food engineering sciences are thus the sciences that are related to the creation of food. Traditionally, this has been mostly interpreted as the scientific field of designing processes for producing or stabilizing foods. More recently, the food products themselves have become more central in the approach of food engineers.

In a technical sense, foods are different from most chemical products by their complex composition and by their very complex morphology. Most chemical products consist of just one molecule (ethylene, styrene, or caprolactam), or a relatively simple molecular mixture of homologs (gasoline and diesel). A chemical product usually does not have a specific structure on larger scales than the molecular scale. Food products typically have hundreds or even thousands of constituents, which are arranged in a very particular structure. The structure is a major determinant of the overall properties of the food product. In contrast to the production of chemicals, the preservation, modification, or creation of the structure of a food is, therefore, a major goal of any production process.

The production of sufficient, safe, and palatable food is a critical issue for society. Therefore, food engineers are employed not only by food processing companies (both the production of ingredients from raw agricultural materials and the production of end products), or by their suppliers (equipment manufacturers and suppliers of packaging concepts), but also by governmental and consulting agencies.

Food Engineering in a Changing Human Society

The spread of humanity over the globe, from the original tropical areas where food is available throughout the year toward areas where food is not available year-round, has been made possible by the preservation of foods. By the storage of foods, one can subsist on foods that were harvested at one specific time in the year.

Food preservation went hand-in-hand with the development of human civilization; one might even argue that food preservation has precipitated civilization as we know it. Foods that are harvested need to be stored in central locations, to ensure the right conditions and to protect them against others that might not have stored sufficient foods. Preserving foods also mean specialization: next to the harvesters, protectors, builders, potters, administrators (to check who would be entitled to the foods), and many others were necessary. The abundance of one particular food in one area, and the abundance of other foods in other areas, then gave rise to trade and development of a commercial system.

Until 1950 – Availability of Safe Foods

Therefore, the activities that food engineering nowadays comprises, are not new, but are as old as humanity. Many techniques have been developed over the millennia. The production of beer and wine has been developed in the near East (earliest findings in Iran and Georgia from 7000 BC); the baking of bread goes back to at least 30 000 years. All those processes were meant to make stable foods that are safe for consumption. They have been developed through experience and trial and error; acquisition and application of systematic insight was not yet a main driver in the development.

One usually only speaks about food engineering as a recognizable field, with the invention of processes as the appertization process by Nicolas Appert at the beginning of the nineteenth century, for the sterilization and stabilization of foods in jars and cans over prolonged periods of time by heating of a packaged product. Although Appert used glass jars, sterilization in tin cans was invented by Peter Durand in 1810. Food engineering was then taken to a next level by the creation of margarine by Hippolyte Mège-Mouriés in 1869 and by the development of pasteurization by Louis Pasteur in 1862.

The basis of food engineering is, therefore, in the preservation of foods: to prevent spoilage by microorganisms and enzymes, and to preserve the nutrients such that the product would stay palatable after opening the package. This remained the primary focus of the field until the middle of the twentieth century. The global development of agriculture and food production ensured the supply of sufficient foods for many, more developed, parts of the world. The increased affluence of the population in the 1960s and later led to more and more attention to the quality of the foods: not only just the availability of safe food safety but also its nutritional and sensorial quality became important.

1950–2000 – Toward Diversity of Foods

Even though food safety remained and remains a *sine qua non* for food engineering, new developments set additional challenges. In the 1950s and 1960s, the population in many countries became more affluent. At the same time, the mechanization and use of auxiliary chemicals (pesticides and

 doi:10.1016/B978-0-444-52512-3.00060-7

fertilizers) made agriculture much more productive, which precipitated a change from a shortage into an abundance of foods. Thus, food products had to be optimized for consumers who now could choose what to buy.

Therefore, the last three decades of the twentieth century gave rise to the development of an ever-greater diversity of food products. The popularity of refrigerators and freezers enabled the development of chilled and frozen supply chains. Also instant products that either needed reconstitution with water or would only need heating up became popular. Cartoons from that time sometimes depicted the future of foods as 'space food,' provided in tubes and pills. This reflected the developments in food engineering, which enabled the production of instant products and pure ingredients.

In reality, the diversity of foods exploded. Although instant foods (soups, potato mash, and whole meals) became available, consumers also got access to fresh (chilled), frozen, stabilized foods, including products that originate from almost any place in the world. One is now comfortable and familiar with Chinese, Thai, Japanese, Mexican, Italian, African, and many more foods and also has access to the ingredients necessary to prepare them.

2000 and Beyond – Food Engineering for Health

Although our affluence increased, our lives changed. People started to consume other and more energy-rich foods. The average family could afford a car, and thus individuals exercised less. At around the turn of the millennium, concerns of public health emerged due to the rising incidence of overweight and obesity in many regions in the world, which is accompanied with a striking increase in diabetes type II, cardiovascular diseases, and some types of cancer. In the twenty-first century, being overweight is just as large a health problem in the world as malnutrition is in areas still plagued by poverty and famine.

The increased concern for nutrition-related health led to a new development, which was toward the inclusion of specific ingredients that were claimed to have a specific, beneficial effect on the consumer's health: the functional foods. These foods do not aim solely at general nutrition, but aim to establish a specific effect on one's health or well-being. Functional foods include foods that are fortified with vitamins or calcium, or with probiotic ingredients (living microorganisms that are claimed to positively complement the natural ecology in the gut), prebiotics ingredients (indigestible fiber that is claimed to positively affect the ecological balance in the human gut), unsaturated fats and oils (e.g., those containing ω-3 and ω-6 fatty acids), ingredients helping in reducing weight (e.g., fiber, but also encapsulated emulsions) or reducing cholesterols levels (phytosterols, e.g., in margarine).

Food engineering was important in several ways. First, the ingredients that deliver the health benefits need to be produced. In many cases, this requires separation and isolation methods to purify the components from their raw materials. Examples are the isolation of lactoferrin, lactoperoxidase, and several fatty acids from milk, the isolation of fiber from milk and other streams and the isolation of, for example, fish oil. In addition, fermentation provided new strains of probiotic microorganisms (mostly lactic acid bacteria and bifidobacteria), whereas enzymatic conversion of lactose yielded prebiotic oligosaccharides.

Second, the ingredients need to be integrated into foods that have good taste and quality. This requires techniques for stabilization of the ingredients (e.g., by freeze drying), encapsulation (e.g., for fish oil), and structuring (e.g., incorporation of phytosterols in margarine). A third, recent contribution of food engineering has been to the understanding of the breakdown of food matrices and the release and bioavailability of ingredients using food engineering concepts in the modeling and simulation of the processes taking place in the gastrointestinal tract.

2000 and Beyond – Food Engineering for Taste

Although the increased affluence has given one more concern about health, it also had the positive effect that consumers worldwide have more time and resources to spend on high-quality food. Dining in a restaurant is now common everywhere, whereas media pays much attention to sophisticated food, through television shows, often with famous chefs, who have become celebrities. The increase in popular interest for the systematic understanding of the changes in foods during preparation, led to the emergence of molecular gastronomy and gastronomic engineering (e.g., This, 2002; Aguilera, 2011). These are new branches of food engineering that explicitly aim at the creation of new sensorial experiences in a restaurant setting (i.e., not foods that are stored over time, but products that are created and immediately served to the consumer). Here, good understanding of the underlying molecular and mesoscopic processes taking place in the food, while being prepared, gives an enormous scope to create innovative textures with various ingredients.

Food engineering has been involved through the development of new processes for the isolation and purification of components meant for these products. Examples of these new processes are the isolation of gelling agents for the spherification of juices (Gibbs, 2011), or the availability of protein isolates from various sources that can be used to form new textures.

Second, food engineering has provided better understanding of the processes taking place within a food matrix during preparation: for example, the better understanding of the denaturation of proteins has led to the employment of cryogenic denaturation instead of heat denaturation to 'fry' an egg. The realization that crispiness is related to the glassy state, created the possibility to have crispy slices made from vegetables, or even liquids.

The field of gastronomic engineering is under full development. Aimed not at very large-scale production but at the creation of individual products, it widens the field of food engineering, and brings it closer to the homes of individual consumers.

2000 and Beyond – Food Engineering for Sustainability

Although the increased affluence created much more comfort and room for enjoyment for people in most of the regions in

the world, this also created an enormous expansion in the use of resources. The use of fossil resources exploded due to the ubiquitous use of cars and transportation, the use of energy-intensive materials (e.g., concrete, steel, and plastics), and the use of fertilizer. The production of food exploded as well; whereas the global population increased by a factor of 6 in the twentieth century, the production of food increased by a factor of 7. At the same time, consumers buy more luxury foods, such as meat. Nowadays, 33% of all cropland is used for feeding cattle, 70% of the land that was previously forested in the Amazon is now used as grazing pasture, and the cattle is responsible for an estimated 18% of all greenhouse gas emissions – more than all traffic in the world.

It is, therefore, not surprising that a third trend (next to health and gastronomy) has been toward more sustainable production. Given the burden that the production of meat is on our resources, there is a trend among young consumers (especially in Europe) to want to reduce the consumption of meat. Although a few become vegetarians, many become 'flexitarians,' willing to forego meat for a few days in the week, but not always. There is thus a growing market for meat analogs and plant-based protein products. Food engineering contributes significantly to the improvement of the palatability of these products.

Food manufacturers and food engineers have in recent years strived for more efficient processes. Process integration (reusing heat and water on several spots in a production process), process intensification (more than one process step simultaneously carried out in the same or smaller equipment), and development of processes that intrinsically use less water and energy for drying are examples.

In addition, many processors or raw materials (cereals, beets, and potatoes) now aim not only to produce their main ingredient(s) but also to use all side streams for high-quality products; this development is known as food biorefining or side stream valorization, and includes, for example, the complete refining of whey into individual proteins, isolates, and other components, but also the use of leftover material for production of bioenergy, the isolation of proteins from leaves, sugar beet, or potato.

Current Fields of Food Engineering

The processing of raw materials into an ingredient or a food that can be preserved and is palatable, generally requires many steps. A sequence of these steps is a process. Typical, large-scale processing plants, as can be found for the production of beer, dairy products, sugar and sucrose or fructose syrups, flour, beverages, canned products, and instant meals, consist of a rather long chain of many steps.

The raw material when received from the fields is usually first cleaned, and soil and stones removed. This is often done by a combination of mechanical action and rinsing with water. The raw material matrix is then opened. This is often done by some degree of disintegration: milling (wheat), flattening (soy), cutting (sugar beet or cane), or mashing (potato). Cells may open up by heating.

In the production of ingredients, the primary extraction of components takes place by extraction (with water, as with sugar beet and cane) or mechanical expression (with oil containing seeds, such as soy, olives, sunflower seeds, and peanuts) often followed by a secondary extraction with solvents (hexane for oils). The extract then needs to be purified, as many other components will have joined the component(s) that were desired. This is often done through centrifugation, sedimentation, filtration, and sometimes through precipitation. Finally, the product needs to be stabilized, which can be done by packaging and heating or by dehydration (e.g., crystallization of sugar or spray drying of a protein isolate). The raffinate (the remains of the matrix after extraction) may be further processed to isolate other components, for it is used as lower value stream, for example, cattle feed, or is discarded.

Nowadays, many end products (pasta sauces, peanut butter, margarines, ice cream, etc.) are composed from individual ingredients; they may, therefore, be called fabricated foods. The product, is created through simple mixing (for liquid products) and heating, baking (for cookies, crackers, and other bakery products), or structured using extrusion (soy-based meat analogs, starch-based expanded snacks, and ice cream) or molding (confectionery and liquorice). When the end product has a high water activity, it needs to be heated for stabilization.

Both in the production of ingredients and in the assembly of end products from ingredients, processes are sequences of a number of steps, which can be categorized into:

- Thermal stabilization (preservation) processes
- Nonthermal stabilization processes
- Cooling and freezing
- Dehydration processes
- Separation and isolation processes
- Chemical and biochemical conversions
- Mixing and structuring processes

Thermal Stabilization Processes

Heating a product inactivates microorganisms and enzymes, which both will change and degrade the food over time, when still active. At the same time, heating also changes the texture of products: vegetable products tend to soften, due to the partial hydrolysis of the pectin in the cell walls, whereas meats will become stiffer due to the denaturation of their protein-based matrix.

Different forms of stabilization by heating can be defined. Blanching is short heating of a product with the aim of inactivating enzymes and microorganisms, but not their spores, which would require longer and more intense heating.

Blanching is a short heating process often for just a few minutes. It is not sufficient for preservation in isolation, but is generally applied before freezing or nonthermal preservation of a product. Even though most processes slow down tremendously in frozen products, chemical conversions, such as enzymatically catalyzed reactions do proceed, albeit at a very slow pace. A frozen product that has not been blanched will slowly degrade under the influence of oxidation (e.g., by lipoxygenases or polyphenol oxidases) and hydrolysis (e.g., by lipases). Blanching also induces some changes in texture that may be beneficial. For example, French fries are blanched before they are (pre-)fried, which rinses some of the reducing sugars from their surfaces, which would cause excessive

browning due to Maillard reactions during frying. Before mushrooms can be canned and sterilized, they first need to be blanched. This shrinks the mushrooms and removes part of the water from the mushrooms, which would otherwise give excessive shrinkage during canning and sterilization. Blanching is generally done by immersion in hot water or by blanketing with steam.

Thermal pasteurization is done by more intensive but still relatively short heating, which inactivates not only the enzymes, but also most of the microorganisms in vegetative state. This is not sufficient to inactivate bacterial spores, and will give a lengthening of the shelf life, but not an indefinite shelf life. Pasteurized products generally have to be stored refrigerated. Many fluids that are heat sensitive, are pasteurized, such as milk, fruit juices, and beer. One form of pasteurization is called high-temperature, short-time processing: this implies heating the product for a short time to a high temperature. The short time ensures that the product quality is not overly affected, whereas the high temperature ensures sufficient inactivation of pathogenic microorganisms.

Sterilization is done by much longer and more intense heating. If the heating is sufficiently long and intense, not only the bacteria in their vegetative state will be inactivated but also bacterial spores. Products that are sterilized can be preserved almost indefinitely. Sterilization in a can or glass jar done for long times is often called appertization. Sterilization usually affects the quality of the product significantly. Proteins are denatured, and may even start to decompose, leading to the formation of sulfur containing off-flavors. Nonenzymatic (Maillard) browning between proteins and sugars, and also caramelization, will lead to a darkening of the color, and may lead to a bitter, 'cooked' flavor. Of course, these effects are not in every product equally detrimental to the taste, so some products can be sterilized more easily than others.

Sterilization is typically done with liquids (milk), but with solid products, such as vegetables, mushrooms, meat products such as sausages, and soups and sauces). Typical packaging used for the solid products are metal cans, glass jars, and more modern, plastic pouches, which allow faster heating and cooling.

Methods of heating

There are various ways of heating products. A fluid is usually heated either indirectly in a heat exchanger, and then cooled in the same way, or directly by injection of steam, followed by rapid expansion and flashing off of the steam. The direct heating and cooling is much faster, and can, therefore, lead to a much better product quality; however, it does require mixing of the product with (condensing) steam, and flashing of steam, which may entrain flavors from the product.

Ohmic heating does not rely on convective or conductive heating through the walls, but relies on the imposition of an electric (AC) current, which heats the product through the energy dissipation due to its electric impedance. As the heat is generated in the product itself, heating can be much faster. It does require the heating to be done with electricity, which is more expensive than using steam.

Other ways of heating products are, for example, using radio-frequency heating (which relies on the application of an alternating electrostatic field with frequencies in the GHz range) and microwave heating, which uses a magnetron type antennae to generate an intensive radio-frequency field. Both types heat the product from the inside and can thus be very fast. Both methods, however, use electricity to heat the product and require expensive equipment.

Nonthermal Stabilization Processes

It is also possible to pasteurize or sterilize a product without heating the product. The potential advantage is that the product will not experience thermal damage and will remain fresher in taste. One of the earliest examples of this is the use of filtration and centrifugation. In the processing of juices and liquid dairy products, the product is filtered using (often ceramic) microfiltration membranes, with pore size of approximately 1 μm. Bacteria are retained by the membrane, whereas the liquid product passes the membrane. The retentate can then be thermally pasteurized and added to the permeate or be used for a different purpose. In the case of a product containing proteins and reducing sugars (such as milk), the separation of the sugars (which pass the membrane) and the proteins (which, due to their aggregation in micelles, end up in the retentate) leads to much less browning and bitterness, and a much better taste. An alternative is the use of centrifuges instead of the membrane (**Figure 1**).

The use of high hydrostatic pressures has gained much attention in the past decades, as it was found that application of several thousands of bars (hundreds of MPa) inactivates bacteria in their vegetative state, but affects the texture and quality of the product much less (San Martin *et al.*, 2002). Although it can be applied to both liquids and solids, the process is most promising for solid products: pressure equalizes with the speed of sound, whereas conductive transport of heat takes many orders of magnitude more time. A few products have already been launched (guacamole, some marmelades, hams, and some fish products). Products are typically packed into

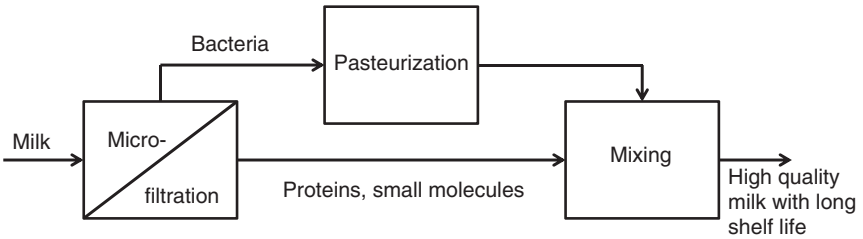

Figure 1 Using a combination of size exclusion and thermal preservation.

flexible plastic pouches, which are put in a pressure chamber, which is then filled with water, and put under pressure. Even though the process is effective for the inactivation of vegetative cells, inactivation of bacterial spores is not possible as of now. Only pasteurization is, therefore, possible at this moment.

Another development is the application of a pulsed electric field over the product (Castro *et al.*, 1993), which has to be electrically conducting for this technique. Typical fields can be up to 5–25 kV m^{-1}; short pulses are needed to minimize the power consumption (and to minimize the generation of heat in the product). The electric field causes polarization of ions against the cell membrane of bacteria, and if sufficiently intense, may induce the cell membrane to form pores, which lead to leakage of the cell cytoplasm, and ultimately cell death. Because bacterial spores are protected by a thick, nonconductive cell wall, they are not susceptible for this type of inactivation, and therefore products can only be pasteurized. A relatively new application of this technique is not for pasteurization, but for mildly opening plant cells, for example, for the isolation of components (sugar from beet or cane, oils, and antioxidants). Owing to the larger size of plant cells, they are opened more easily and thus lower electric fields are required.

Other nonthermal methods that have received attention are, for example, the use of intense pulses of light (especially UV light inactivates microorganisms effectively, Gomez-Lopez, 2007), which mostly works on the surface of products. It is, of course, important that the light pulses do not discolor the product, so this is not applicable on any product. Some people have claimed microbial inactivation with the application of intense magnetic fields. Although the mechanism that would be responsible for this is not completely clear, research in this field continues.

Finally, some endeavors were made in product stabilization using bacteriophages: viruses that attack spoilage or pathogenic bacteria. This type of biological pasteurization is interesting because exceedingly small amounts of phases are needed, and they multiply themselves; and resistance against the phages is unlikely, because the phages evolve with the evolving bacteria. However, most food producers are uneasy with adding viruses to their products, even though they are inactivated (usually thermally) in the final product. It remains to be seen whether this technology will, therefore, be allowed and applied on larger scales.

Cooling and Freezing

Cooling a product to 0–4 °C will slow enzymatic and nonenzymatic processes, and growth of bacteria. It has, therefore, become the standard for preserving perishable products at home, and many supply chains are now refrigerated: for example, meat, vegetables, many juices, and dairy products. An emerging problem with the ubiquitous use of chilling (refrigeration) is that psychrophilic bacteria, which can grow well at low temperatures, are becoming more prevalent.

Although most quality changes in a product are slowed down at lower temperatures, they do not stop completely; therefore, only storage times of days to weeks can be achieved. For longer preservation, the product may be frozen. By cooling to approximately −20 °C, most of the water in the product is captured in ice crystals. As the ice crystals only contain water, the surrounding matrix increases in concentration, and will obtain a lower water activity, which contributes to the longer shelf life. Even in the frozen state many enzymatic processes do not stop completely, and therefore the product's enzymes need to be inactivated by blanching. In this way, a product can be stored over longer time.

Freezing does compromise the quality of the product. The formation of the crystals means that there is displacement of other material from around the crystal. Thus, the matrix of the product is damaged. It is well known that freezing vegetables that are high in moisture leads to loss of the turgor (stiffness) of the tissue: the once firm and stiff vegetable now becomes limp and after defrosting will leak much juice. Meat will also show loss of juice after defrosting: also here the cells are damaged, leading to leakage of the cell cytoplasm, even though the firmness of meats is not affected to the same degree.

The extent and type of damage depends on the rate of freezing. Slow freezing will result in large crystals and thus extensive damage to the product's structure. Fast freezing of vegetables will lead to substantially less damage because most crystals will remain small enough to fit inside the cells, and therefore the cell walls are not compromised. Therefore, many new developments deploy methods to allow faster freezing. Although freezing is usually done in a blast freezer (blowing frigid air around the product) or, for packaged products, in a bath containing brine or another nonfreezing liquid, one can also immerse the product in liquid nitrogen or bring it in contact with solid CO_2.

Dehydration

Any spoilage process needs moisture. Bacteria do not grow at a water activity lower than approximately 0.85; and molds do not grow below a water activity of 0.8. Although in many traditional products a low water activity is attained by adding salt (a saturated NaCl solution, containing ~36 wt% salt, has a water activity of ~0.76) or sugar (a 60 wt% solution of sugar has a water activity of ~0.9), the most straightforward way to achieve a low water activity is to remove part of all of the water in the product.

Owing to the small molecular weight of the water molecule, one has to remove most of the water to obtain a significant reduction of the water activity. Traditional drying is usually done by exposure to air, preferably with the assistance of solar heating; examples are the drying of tomatoes, fruits, fish (e.g., the Norwegian lye fish), meat strips, and spices beans. Unfortunately this process is not well controlled, depends on the weather conditions, and is not easily scalable to larger product capacities.

Therefore, solid products are industrially dried using tray driers, in which products are exposed to hot or dry air for a considerable time. This is done in the preparation of, for example, not only raisins, dates, prunes (dried plums), figs, apricots, peaches, apples and pears, cranberries, blueberries, cherries, strawberries, but also with pasta and pastries. Typical drying times may range from minutes to several hours, for larger products that contain much water.

Liquid products are usually first concentrated in an evaporator. Here, the product is heated indirectly possibly at under pressure using steam. About the same amount of moisture will evaporate from the product as the amount of steam that condenses in the heat exchanger. Evaporators can be easily cascaded, in which the vapors from one stage, are condensed in the next stage and thus to evaporate another amount of moisture from the product. Five- or six-stage evaporators are usual in large operations (e.g., in processing juice from sugarcane or beet or in dairy processing). The resulting concentrated slurry may already have lost most of its moisture and have up to 80 wt% solids; however, this is not yet sufficient, and the slurry is then dried. As evaporators cost a lot of energy to evaporate the water, in newer plants part of the concentration is done with reverse osmosis: Here, the water molecules are forced, under high pressure of 60–100 bar, to permeate through a thin membrane, whereas all other molecules, being larger and not soluble in the membrane, are retained by the membrane. This process is limited by the difference in osmotic pressure between the feed (a concentrated solution) and the permeate (essentially water), and therefore the last part of the concentration process is often still done through evaporation.

A spray drier is used for fluid products that are heat sensitive. Here, the slurry is atomized using great pressure into tiny droplets, which are injected into a large space that is filled with hot air. The air heats the droplets, which remain relatively cool to the (fast) evaporation of the moisture; the product, therefore, remains substantially cooler than the surrounding air. The typical residence times of the droplets can be very small: down to a few seconds. After this, the droplets will have lost most of their moisture, and have become solid. They often need to undergo a final drying step to remove the last remnants of the moisture, and cool it down, to ensure that the powder will not be sticky (i.e., be in the glassy state). A fluidized bed drier is often used for these last steps; a bed of particles, which are kept in motion by an upward air flow, ensuring a very intensive air–solid contact and intensive mixing of the powder. This fluidized bed also leads to agglomeration of the primary particles from the spray drying chamber, which are 'glued' together into much larger agglomerates. This is important as the small primary particles (which can be as small as a few micrometers) are detrimental to the health of the workers handling and using the powders.

For products that are not that heat sensitive, a more efficient process is drum (or belt) drying. Here, the slurry is applied in the form of a thin film onto the metal surface of a drum, that is heated with steam on the inside. A typical temperature of the drum is 120–140 °C. The drum rotates slowly, and because the product film will start to boil its moisture away, the film will become dry after some time, and can be scraped off the drum when it has rotated by some degree. Although this process requires less energy, it exposes the product to more intensive heating, which may reduce the quality of some products. The product coming off a drum dryer may have a flay morphology, and may be grinded to smaller particle sizes when required.

For products that are extremely heat sensitive – for example, products that rely on flavors, such as coffee, tea, or that contain proteins that should not be denatured – one can apply freeze drying. Here, the slurry is first frozen and then milled into small grains while being frozen. The product is then spread out over trays, which are inserted in a vessel, which is evacuated. The low pressure causes the ice to be sublimated. Owing to the sublimation process that requires a lot of heat, the trays are usually heated. The end product is highly porous (ice crystals were present which leave open pores), and has not been exposed to any high temperature. The quality of the product can, therefore, be very high, albeit at a much large use of energy.

Separation and Isolation Processes

The food industry can be roughly divided into (1) processors that stabilize and finish products that come off the land and can be eaten in that form (vegetables, meats, and fruits), (2) processors that produce ingredients from raw materials, and (3) processors that assemble ingredients (and raw materials) in end products. The second category is a very important one and comprises the sugar industry, much of the potato, soy, corn, and wheat industry, and a large part of the dairy industry. Many of the foods that one consumes are prepared from ingredients, and almost all products contain separately isolated ingredients. Separation and isolation of components from the raw produce is, therefore, an extensive part of the food industry. A few classes of separation processes will be discussed without any claim on completeness.

Phase separation and mechanical isolation

An ingredient may be released by mechanical means. Pressing soy beans (that are flattened and heated to denature the cell membranes) or olives, will result in the oil being pressed out. Although this oil is not pure, and still contains particles from the original matrix, and will contain water droplets and aqueous components inside those, the oil can be of high quality because its thermal history is limited. In olive oil, this is called the virginal pressing.

Milk fat is conventionally removed by centrifugation: the fat, being lighter, creams up, and can be removed easily. In renneted milk, the whey can be removed from the precipitate by pressing. In the processing of potatoes, the potatoes are first mashed, which leaves a suspension of starch granules in an aqueous phase that contains most of the other components. The starch may be removed by hydrocyclones, in which centrifugal force is used to mechanically separate the starch from the aqueous solution.

In case the phase to be removed consists of small particles ($<10\,\mu m$), which do not have a large difference in density with the surrounding medium, filters can be applied. Beer and wine are usually clarified by filtration after fermentation, to remove the last yeast cells from the liquid and obtain a clear product. First, the product is mixed with a filter aid, typically highly porous particles made of silica or similar. The suspension is then filtered; the particles are retained, and incorporate in their pores the fine particles (cells or debris from disintegrated cells) that were present in the product. The filter aid plus retained material is waste. Microfiltration is a newer process. Here, a membrane (thin filter) is applied that typically has pores in the range of 0.1–10 μm, allowing the removal of particulates without the use of filter aid. A crossflow over the

membrane is used to keep the retained material from accumulating on the membrane.

Macromolecular separation: Ultrafiltration, solubilization and precipitation, and extraction

The clear liquids that are obtained from the phase separation operations described above can be further refined. One way, used extensively in the dairy industry, is ultrafiltration. This is the use of a membrane with very small pores, typical 1–10 nm. Small molecules can pass relatively unhindered through these pores, and are pushed through by a typical pressure difference over the membrane of 2–15 bar, whereas macromolecules such as proteins and large carbohydrates are retained. The accumulation of these components on top of the membrane is kept in check with a strong crossflow. Although this process does allow for separation of proteins that are in solution, it does not allow the separation of macromolecules that are still in the solid phase, and it hardly allows the separation of macromolecules from each other.

In many cases, solubilization and precipitation is used. In the production of caseins from milk, the liquid is acidified, which induces precipitation of the casein, but not of the whey proteins. The precipitate is then isolated, washed, and neutralized, giving relatively pure casein. In the case of a protein concentrate from, for example, soy, the soy that has been heated and flaked to open up the cell structure and defatted by pressing and extraction with hexane, is contacted with a mixture of ethanol and water (or in some cases a low pH aqueous solution), which solubilizes much of the carbohydrates in the soy flakes (and some of the proteins). The remaining flake is much richer in proteins, and can be isolated and dried to form a soy protein concentrate. Although this product is still rich in (insoluble carbohydrate) fiber and only consists approximately 70% of protein, a soy protein isolate is much purer (90% protein). It is made by first solubilizing the proteins themselves from the soy flakes in water, isolating the solution, and then lowering the pH such that the proteins precipitate. They can then be isolated, and dried to form a much purer protein fraction. Other protein isolates (from pea, lupine, or other crops) are made in the same way.

The extraction process is quite similar: a solvent is used to remove one (group of) component selectively from a solid matrix. Soy oil is isolated in this way: after flaking and heating to open up the cell matrix, and after mechanically pressing most of the soy oil from the flakes, they are contacted with hexane, which dissolves the oil. The flakes are separated, heated to evaporate the hexane that is left behind in the flakes, and the hexane is evaporated (distilled), to yield the oil as bottom product. Although extraction processes are common household processes (preparation of tea and coffee), they are also quite common in the decaffeination of coffee beans (usually with dichloromethane or supercritical carbon dioxide as solvent), and in the isolation of specific, highly valuable components, such as essential oils and flavors and fragrances.

Isolation of small components: Nanofiltration, ion exchange, and chromatography

In many cases, streams contain small components that may be valuable or may have to be removed before the stream can be discarded: small carbohydrates, peptides, and minerals. Small carbohydrates, such as lactose, may be removed by nanofiltration: filters having pores that allow the passage of molecules of 100–1000 g mol^{-1} molecular weight, but not the passage of any larger molecules. Thus, by choosing the appropriate membrane, one can retain lactose, whereas having water and minerals permeate the membrane. By choosing a membrane with particularly small pore size, one may even separate divalent from monovalent ions (divalent ions have a larger hydration mantle and are thus larger in an aqueous environment).

Ionic components may be removed with ion exchange resins. These are swollen polymeric materials that contain many charged groups, which are paired with counter-ions in solution. Beads of these resins are packed into columns. The fluid flows through the bed and comes into contact with these beads. Ionic components pair up with the immobilized ionic groups in the resin, effectively immobilizing these components from the feed. By later displacing them with another salt, they can be isolated. This way not only divalent cations (e.g., calcium and magnesium) are often removed, but also how individual proteins can be separated based on their ionization.

For very specific, high-value components, size exclusion chromatography may be used. This method, which was originally developed in the pharmaceutical field, is not only used for purification of high-value proteins but also for the isolation of fructose in the preparation of high-fructose syrup. Here, a column of stacked, swollen beads, which have very small pores is used. These pores are accessible for smaller molecules, but much less for larger molecules; their molecules are too large to easily fit inside the pores. Many of the small molecules diffuse into the pores, and are retained for some time in the beads, whereas larger molecules are excluded and simply flow with the fluid. Thus, a separation in time is achieved. A new development is the use of affinity chromatography, in which ligands are immobilized onto carrying beads (themselves stacked into a column), which may complexate with specific components, removing them from the fluid. Affinity chromatography also originates in the pharmaceutical industry, but now finds a few applications in the food industry, especially in the isolation of specific proteins.

Crystallization

Some products, such as sucrose, lactose, salt, and fats and oils are separated by crystallization. A crystal is usually made up of only one molecule (possibly with some water in the lattice), and having a component crystallize and then removing the crystals is an effective way of separating such a component. Crystallization can be done by cooling a saturated solution (which then becomes supercooled) or by evaporating moisture from a saturated solution (which created a supersaturated solution). In both cases, crystals will be formed. As inclusions may be formed, crystallization often has to be followed by resolubilization and recrystallization to form even purer materials.

Chemical Changes to Produce Ingredients and Products

Although many ingredients can be directly isolated from agricultural raw materials, in a few cases much more highly

valuable materials can be obtained by chemical or biochemical modification.

One example is the hydrolysis of (wheat or corn) starch into glucose syrup, which is an ingredient for the beverage industry. The starch is isolated (see Section Phase separation and mechanical isolation), and heated to above 60 °C, which gelatinizes (solubilizes) the starch from the starch granules. The enzyme α-amylase is added, which hydrolyzes the glycosidic bonds between the glucose units in starch, and reduces the starch into small oligosaccharides (maltodextrins). The subsequent addition of gluco-amylase, capable of hydrolyzing the last glycosidic bonds, leads to the conversion of the starch into glucose.

High-fructose syrup is produced by converting the glucose, using the enzyme glucose (or xylose) isomerase, partly into fructose, which is sweeter. One may then use size exclusion chromatography to purify the fructose, and recycle most of the glucose back to the conversion.

Sports drinks are often prepared by partially hydrolyzing proteins with the help of hydrolytic enzymes (proteases); the hydrolysate is already partly digested and can be taken up much more quickly by the body to help a sportsperson restore his or her performance. Almost fully hydrolyzed proteins are used for hypoallergenic infant formula for children with bovine protein allergies: The hydrolysates do not have the protein structure anymore, and therefore do not trigger the immune response.

A more modern example is the production of galacto-oligosaccharides, which are not only a prebiotic, required in infant formula, but are also associated with boosting the immune system and mitigating the development of allergies; they are thus also added to a variety of prebiotic drinks and products for both children and adults. They can be produced from lactose with the help of galactosidases, enzymes that may hydrolyze or synthesize lactose into oligosaccharides, depending on the reaction conditions. Fructo-oligosaccharides, having similar properties, can be prepared enzymatically from saccharose, or by enzymatic hydrolysis from inulin (Figure 2).

Structuring Processes

The properties of an end product not only depend on the molecular composition, but also to an even greater degree on the way that these ingredients are positioned in the product. The structure is a major determinant of the properties of the product.

There is a range of processes that is developed for structuring products: baking processes, extrusion processes for making snacks, pasta, par-boiled products, and even ice cream, whereas some intermediate products (powders, granulates, and tablets) are structured to improve their ease of handling and ease of incorporation into an end product.

Structuring end products

In baking, a dough or batter is first prepared by combining ingredients (flour, fat or butter, possibly a protein source such as eggs, sometimes sugar, and flavorings) into a material that allows mixing and the development of some kind of deformable structure. In wheat dough, this is initially the network formed by the gluten. This dough is then stored to allow leaving by fermentation or a chemical reaction (in case of the use of baking powder), and the structure is fixated by heating in an oven. In many cases, the original structuring role of gluten or fat is transferred to another ingredient: in baking

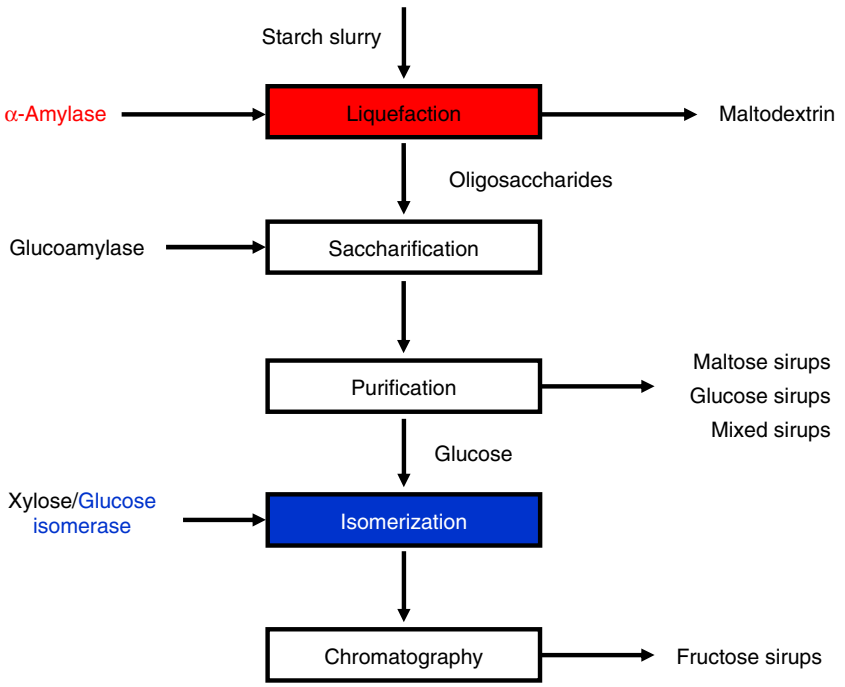

Figure 2 The process for making high-fructose syrups involves the enzymatic hydrolysis of starch into oligosaccharides and glucose, the enzymatic isomerization of glucose into fructose, and chromatographic enrichment of the fructose syrup.

bread the starch that retrogrades to form a gel; in the case of many cookies, the sugar.

Extrusion is basically the mixing, dissolution, and deformation of a mixture under high stress, heating, and the subsequent squeezing of the slurry through a small die. The conditions inside an extruder can be well controlled. This is important, for example, in the production of pasta, where the starch needs to gelatinize but not melt (i.e., starch granules need to swell but not disintegrate) and the gluten needs to form a good network. Inside an extruder, the pressure can be set to as high as 30–40 bar, allowing the temperature to rise far above 100 °C, without having any evaporation. This high temperature melts or dissolves most components, and as soon as the product is squeezed through the die, the excess moisture will flash off. This leads to a sudden expansion of the product, which is solidified almost instantly by the loss of moisture and reduction in temperature. Thus, a porous, crispy product results. This is the basis of the production of many snacks.

A relatively simple structuring process for multiphase liquid products (emulsions or foams) is a homogenizer: an emulsion is squeezed through a small hole. Especially at the compressional (downstream) side, larger droplets break up into smaller ones, allowing the product to become more stable against creaming or other forms of instability. Colloid mills and ball mills impose a very strong deformation field, to much the same effect. A relatively new structuring process for emulsions is membrane emulsification. Here, a to-be-dispersed phase is pressed through the small pores of a microporous membrane, that is strongly wetted by the continuous phase that flow over the downstream side of the membrane. The dispersed phase emerges at the mouths of the pore on the surface of the membrane, in the form of small droplets, which are ultimately detached and taken up by the continuous phase flowing over the membrane. By using microengineering methods, it is possible to have spontaneous detachment of the droplets, which can lead to monodisperse emulsions (Van Dijke, 2010). This very new development is not yet used on larger scale but holds much promise for future emulsion products.

Structuring ingredients

Spray drying processes are often also structuring processes: the small primary droplets partially coalesce and form agglomerates that may have significant porosity. Subsequent further processing in a fluidized bed may reduce or increase this porosity to improve the processability of the powder, whereas the addition of other components to the fluidized bed may lead to an outer layer of another component. Spray- or freeze-dried products are often coated with some lecithin, to reduce their hydrophilicity, which improves their dispersability in water and ultimately improves their reconstitution properties. Crystallization is by definition a structuring process because the crystal lattice type shapes and sizes of the crystals largely determine their properties in terms of processability and dissolution properties.

Crystallization for structuring is important not only for the classical crystalline products (sucrose, lactose, and salt), but also in most solid, fat-based products, such as butter, margarine, chocolate, and ice cream. The 'soft solid' character of these products is created by cooling the mixture, whereas deforming, to the right degree of supercooling, which induces the formation of small crystals. When the product is put to rest, the crystals form a network that gives the product its consistency. Hence, these products are usually made in a scraped surface heat exchanger or similar, or sometimes even in an extruder, and then put to rest to have the crystals age and the network form.

Education in Food Engineering

Food engineering education has always relied onto two pillars: unit operation design and practical courses. The theory is usually on methods to design unit operations, based on relations that correlate the behavior of materials and products under different conditions, such as fluid behavior, vapor pressures, and water activities. Second, exposure to practice during practical courses (i.e., in pilot plants) gives the students a feeling of the scales and phenomena on larger scales. In many curricula, internships done within an industry augments this experience and prepares them for the situation in a real factory.

In recent years, the present-day technology is changing one's perspectives. The ubiquitous presence of information, via computers, tablets, and cell phones means that the task of education shifts from the supply of information toward guidance of how to use and sift data and information. At the same time, geographical distances become less important: email and Skype are available to anyone, and distance learning and massively open education are becoming commonplace, allowing students to share classes while being in different parts of the world.

In addition to this, the nature of the scientific discipline has changed with the availability of massive computational power. A large part of food engineering used to be on how to interpret complex phenomena and relate it to the large-scale behavior of a system: for example, predicting mass or heat transfer rates in systems exhibiting turbulent flow, or non-Newtonian properties. The development of computational fluid dynamics (CFD), particle- and agent-based modeling techniques and process system simulators (e.g., Aspen Plus, SuperPro Designer, and many others) have made it possible to accurately model the behavior on small scale and quantitatively predict the behavior on larger scales.

Massively Open Online Courseware

Traditionally, the courseware developed by universities and polytechnics used to be proprietary; only available to students who are enrolled in a program within that institute. The omnipresence of internet has made it difficult to retain the materials within the institute, however; therefore, a number of institutes have made much of their courseware freely available. At the same time, they offer 'massively open' courses and lectures through the internet. Attendants can then be assessed online, and ultimately obtain a certificate. Although this is not a replacement of the traditional academic and technical curricula, it does make some of the material available for anyone – the moment he or she finds the need for it. This is in line with the Connectivism theory (Siemens, 2005), which states,

following Vygotsky's zone of proximal development (Vygotsky, 1978), that knowledge is generated through laying connections.

This development has the potential to revolutionize and democratize teaching. Food engineering, with its heavy reliance on computation and design challenges, may be very suitable for this approach. The approach is opposite to the model of teacher–tutor system, which allows the student to have direct contact with the teacher during the execution of relevant tasks. This model is the basis of most academic education, especially during practicals, working classes, and thesis preparation phase. This model may be more prevalent in continental European universities, which lay more emphasis on the concept of 'Bildung'; personal development instead of acquisition of skills (e.g., Watson, 2010). The massively open online courseware approach complements this, and will find its own niche in a world that is saturated with information but not with insight.

Simulations in education

Many of the engineering sciences are involved in predicting behavior of products or processes on larger scales from properties on small scale. Examples are the prediction of heat or mass transfer rates based on viscosities, flow rates, densities, and similar; or the prediction of the stability of an emulsion based on droplet sizes and rheological behavior of the continuous phase. This is usually done through correlations, which correlate the behavior under different conditions and in different system. CFD is the technique to directly calculate the behavior of a system on small scale, over a fine grid or large collection of elements, and from this, numerically integrate toward the behavior on large scale. Modern CFD methods can even directly simulate part of the turbulence at high Reynolds numbers (large-eddy simulations) and from this predict the influence of turbulence. Development of methods as dissipative particle dynamics (e.g., Moeendarbary *et al.*, 2009) and lattice Boltzmann methods (e.g., Kulrattanarak *et al.*, 2008) has made it possible to even simulate the behavior of the full complex, multiphase systems, which foods generally are.

Education has to respond to this by introducing and using these methods in the curricula, and by adapting the core of the field, from correlations and general guidelines, toward how to use these computational tools, and extract the right (generalizable) insight from it. This will make it possible to have more emphasis on the complexity of foods, and from there be able to make the connection to the sensorial and digestive properties of the produced products – these were traditionally out of scope due to the complexity involved.

Thus, in the next decade one will experience major changes, not only in the methods of education but also in the number, spread, and background of the recipients, and in the type of the scientific subjects.

Future Challenges for Food Engineering

Although food engineering is a mature discipline, offering suitable operations for the production of a very wide range of products and ingredients, there are large societal challenges that need to be addressed by the field.

Although part of humanity is still suffering from undernutrition, they are now outnumbered by the number of people suffering from overnutrition. Obesity is the largest pandemic in history and its incidence is increasing rapidly everywhere in the world. Overweight and obesity are closely correlated with cardiovascular diseases, with the occurrence of diabetes type II, with different forms of cancer, and with a variety of symptoms called the metabolic syndrome. Understanding how the production of new foods by new processes may help to mitigate this problem is becoming more and more urgent.

The global population is rising, from approximately 7 billion in 2013, to approximately 9–10 billion in 2050. On top of that, the number of affluent people in many regions rises, which means that consumers are able to and want to buy more luxury foods, such as meat and processed foods, which require more agricultural and fossil resources to produce. It is estimated that in 2050, one will need approximately 70% more primary production to cope with both effects. At the same time, our fossil resources are becoming more difficult to find and exploit, which makes them less available and will lead to more environmental stress in their production. Many agricultural lands are overexploited to show serious signs of degradation by erosion or depletion, which leads to the suggestion that 70% increase in production cannot be achieved without a serious reconsideration of the postharvest chain. At this moment one loses approximately 30–50% of all produced foods somewhere in the chain. This shows that there is potential to improve our food production system and find an answer to the rising demands and stagnating sources.

A third challenge is the emergence of the so-called bio-based economy (Langeveld, 2012). As the development of fossil resources is a major force in our global economy, one has known that these fossil resources are finite. The unbounded rate at which these resources were made available has led to an explosion of the global population and has changed the face of the Earth. Now, one faces a transition back, from a fossil resources-based economy, toward a bio-based economy, in which one has to use bio-based materials and energy, also for nonfood purposes. But because our population has grown by at least an order of magnitude over this period, one needs to become much better in the use of these biological resources. Already one has seen tension over the 'food or fuel' issue; this may become more serious if one does not develop an economy in which one can produce both foods and materials and fuels from the same resources.

There are a number of scientific and technological developments that may help us in approaching these challenges with some vigor.

Food Digestion Engineering and Human Health

The nutritional sciences have identified many of the mechanisms that underpin the metabolism of nutrients. Food engineering has developed sophisticated processes to produce products with the right sensory properties. It is amazing that not much is known about the part between the product as it is eaten and one's metabolism.

The process of disintegration and dissolution of food products in mouth, stomach, and intestines, though very

complex, shares many characteristics with the processes food engineers have applied for the assembly of ingredients and products, and in recent years, they have started to apply their methods to the understanding of the digestion process. Experimental rigs as simplified simulators of the gastrointestinal tract may contain a semipermeable membrane (mimicking the small intestine wall; Tharakan *et al.*, 2010). Peristaltic flow is generated by a pump, whereas pneumatic squeezing cuffs generate local segmentation. This has been used to study the effect of viscosity and segmentation on the uptake of riboflavin, which could then be described relatively as simple food engineering principles. Others have used simple tanks-in-series models to describe the fate of microorganisms during passage through the intestinal tract in animals and humans.

Singh and coworkers have studied the behavior of food in the stomach and developed various *in vitro* stomach models, for example, a relatively simple model stomach system and a more complex human gastric simulator (Kong and Singh, 2008, 2010). Products undergo a number of changes during primary digestion in the stomach. Gastric juices penetrate into the product. Acid and protease dissolve some components, which induces porosity, facilitating the penetration of gastric juice. With increasing porosity, the outer layer becomes fragile, and the mechanical action of the stomach then erodes the outer layer away, exposing the less digested parts. This may give rise to a steady erosion of the product when the penetration is not too deep, or a mechanism in which the product first swells, due to the absorption of the gastric juice, and only later disintegrates (Kong and Singh, 2008, 2009). Generally, cooling of foods favors a transition from an erosion mechanism to a disintegration mechanism.

Other studies have modeled the flow and muscular action in the gastrointestinal tract, using CFD, which showed, for example, that ingested fluids may bypass the solids foods that are digested and are already present in the stomach (the so-called Magenstraße), and that the antrum contraction, creating a jet back into the gastric body, is important in the disintegration of solid foods.

Following *in vivo* digestion is much more complicated, and simplifications are required. In many cases, animals are used for this – invasive studies are possible, even though there are differences in the gastrointestinal tract characteristics. For example, Bornhorst *et al.* (2013) showed in pigs that although the starch digestion from brown and white rice is similar, that of proteins was much slower in brown rice. They showed that the pH in the stomach is nonhomogeneous and the amount of gastric juice depends on the type of rice, whereas at the same time bran was shown to accumulate in the stomach.

Several noninvasive methods have become available for study of the digestion process. In some cases, probes have been used to measure contractions or other conditions (Vassallo *et al.*, 1992), whereas magnetic resonance imaging studies could show the typical motions of the stomach while digestion takes place (Pal *et al.*, 2007).

One may expect that better insight in the mechanisms of digestion will lead to a better design of food products (and processes to prepare them), targeted to achieve the right effects in humans: better controlled satiety to mitigate overconsumption, reduction of the glycemic index without compromising the taste, less inactivation of pro- and prebiotics during passage through the upper gastrointestinal tract, and better support of the microbial ecology in the lower gastrointestinal tract. One might even expect that if one knows how one's body processes foods, one may adopt some of these principles into production processes in the food industry.

Food Production in a Bio-Based Economy

Since the nineteenth century, one has developed an economy that was based on using fossil resources, such as coal, oil, and gas, which, although finite, can be supplied with almost limitless amounts as long as they have not been depleted. The current volatility in prices of fossil resources shows that this depletion is not far off. A short-term solution is at hand using shale oil and gas, but these are only extracted at great environmental costs. In the long term, one has come to realize that one has to find renewable resources. Biomass and agricultural materials are in that category.

At the same time, one knows that one's limitless emission of components such as CO_2, CH_4, and many others, has led to global warming, which in its turn gives rise to instabilities in the local climates around the globe. One of the routes to mitigate these effects is to use resources that sequestrate some of these components during their creation. This is exactly what happens during the growth of agricultural products.

The biorefinery

Traditionally, food ingredient industries concentrated on the production of one ingredient: sugar from sugar beet or cane, starch from potato or wheat, or cheese from milk. There is an increasing awareness that the total production system can be adapted to the complete conversion of the raw material into valuable products. The Dutch potato processor Avebe, for example, a traditional producer of potato starch, now also produces a number of potato protein fractions and isolates with excellent technical and nutritional functionality, from the stream that used to be a waste stream from the production of starch. Many industries consider isolating valuable components from waste streams, or changing their production method such that the waste streams can become valuable products.

Parallel to food processing, a new industry has arisen, that processes raw agricultural products not in foods, but in nonfood products; mainly biofuels. The first generation of these factories converts the starch in corn, sugarcane, or other products into bioethanol. This is done through a rather traditional fermentation process: the corn is milled, mashed, and diluted with water, and fermented with yeasts, leading to a beer that has 3–5% ethanol. This beer is distilled into almost pure bioethanol. The rest is dried into spent grains and generally used as cattle feed. The large-scale implementation of this technology has led to a rise in corn prices, leading to social unrest in many countries. Further, the widespread cultivation of corn has replaced part of the soy production in the United States, which was taken over by other countries, such as Brazil, which had to clear parts of the Amazon rainforests.

The second-generation processes takes into account that nonfood production should not compete with food production. It uses indigestible fractions, usually cellulosic or lignocellulosic in nature. These are conventionally waste, or

are burned for heat or energy; however, in many cases dehydration of these streams requires too much energy to make this a viable option. By using enzymatic treatment, it is possible to digest and convert these materials into fermentable fluids. Although the current options are not yet up to par with the efficiency of the first-generation feedstock, they are improving rapidly, and will soon be applied on large scale.

A lot of research goes into the development of new crops for nonfood products that do not compete with food production. An example of this is the growth of (micro-)algae. These organisms are efficient and fast growers, and grow in fresh water or sea. Cultivation of a sea area the size of Portugal would suffice for the transport fuel consumption of Europe (Wijffels and Barbosa, 2010). They can accumulate large amounts of lipids, which may be used as biofuels, whereas the proteins may be used for the production of plastics, or, potentially, might be interesting for feed or food production as well. The main bottleneck is that the concentration of microalgae in the water is small (maximum a few per cent), which implies that harvesting is inefficient. Finding ways to harvest and process these algae efficiently is an area of major development. One may envisage that – when this type of biorefinery takes off in large scales – the availability of large amounts of raw protein may transform the fields of feed and food science.

Food Micro- and Nanoengineering

The beginning of the twenty-first century was accompanied with the rise of micro- and nanotechnology – the technology of systems that have a dimension between 0.1 and 100 μm (microtechnology) and between 1 and 100 nm (nanotechnology).

Microfluidics already have an impact in the field of sensor technology, which will allow the measurement of other and more parameters. The metal–oxide–semiconductor field-effect transistor-based pH sensor is now not only common, but is also applied as ion selective field effect transistor to analyze for specific ions. The so-called micrototal analysis systems form small labs-on-a-chip, allowing for complex analyses, up to complete chromatographic, and even NMR analyses. Taste receptors have been placed on chips, allowing for direct measurement of affinities between flavors and these receptors.

Microfluidics will also have an impact on the production of foods. Microsieves are membranes made photolithographically from silicon wafers, and can have an active layer as thin as 0.1 μm, have a porosity up to 80%, and have completely monodisperse pore size down to approximately 20 nm. Metallic microsieves, made through electrodeposition, are now available, which will have an impact on membrane separations.

Although membrane emulsification was developed in the 1990s (Nakashima *et al.*, 1992), it has obtained a new impulse through the development of the microchannel systems (Kawakatsu *et al.*, 1997), basically microfluidic devices with transverse channels of specific shape, that spontaneously form droplet when a to-be-dispersed phase is pressurized through them. Systems such as the edge-based droplet generation type, show that up-scaling to practically relevant yields is possible (Van Dijke *et al.*, 2010). Thus, microfluidics may not only lead to better products, such as completely monodisperse emulsions, but also to new products, such as stable multiplex emulsions, in which ingredients may be encapsulated, or which could be used in low-calorie products.

The trend toward the use of ingredients that have a specific effect on one's health (pro- and prebiotics, antioxidants, micronutrients) also motivates the quest for product forms that allow for 'smart release' of components, protecting these bioactive ingredients in some parts of the gastrointestinal tract (e.g., the stomach), but releasing them in others, activated by some form of trigger (e.g., in the duodenum or colon). Nanotechnology may well bring us these types of encapsulates.

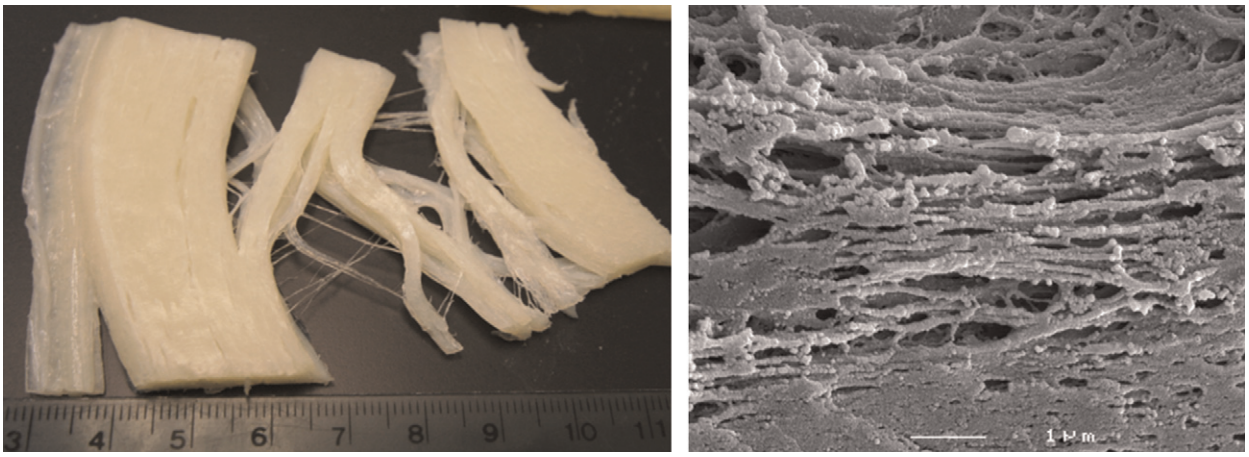

Figure 3 An example of directed self-assembly: Hierarchically fibrillar protein structures made by shearing a 30 wt% dispersion of calcium caseinate that is slowly solidified by crosslinking with transglutaminase. The structure was shown to consist of fibrils of ~100 nm diameter, packed into bundles of ~100 μm thick, which themselves are arranged into larger scale bundles evident in the left-hand side pictures. Reproduced from Manski, J.M., van der Goot, A.J., Boom, R.M., 2007b. Formation of fibrous materials from dense calcium caseinate dispersions. Biomacromolecules 8 (4), 1271–1279, with permission from American Chemical Society and Manski, J.M., van der Zalm, E.E.J., van der Goot, A. J., Boom, R.M., 2008. Influence of process parameters on formation of fibrous materials from dense calcium caseinate dispersions and fat. Food Hydrocolloids 22 (4), 587–600.

The farthest, yet perhaps most rewarding step would perhaps be the 'positional assembly' of food ingredients into a specific structured matrix. Several groups work on food printers, which, however, do not yet allow for the creation of structure below the level of 10 μm (Lipton *et al.*, 2010). However, just like any microtechnology, this printing technology obeys a scaling relation similar to Moore's law: every year, the details that can be made are smaller.

The use of directed self-assembly, in which the natural tendency of molecules to cluster together is steered with the help of a larger-scale field, may allow for the creation of structure even below 100 nm (Manski *et al.*, 2007a,b). That may ultimately lead to meat-like structures created with plant proteins, which would help in creating products that are more sustainable (e.g., plant-based protein products replacing meat products; **Figure 3**).

Conclusion

Although food engineering is a mature field, there are major societal challenges that will transform the field in the next decades: global concerns about health, sustainability, and the coproduction of food and nonfood products. The field can respond by absorbing the new possibilities that arise from new scientific and technological possibilities: new simulation instruments based on the unprecedented computational power available, new possibilities from the fields of micro- and nanotechnology.

Food engineering education will follow suit by employing more digital facilities, shifting the emphasis from understanding the detailed mechanisms, toward synthesizing process systems, and predicting the taste and health impact of products even before the products have been made.

Glossary

Health claims Statements that are made in reference to the positive nutritional value of a food. Regulations dictate specific rules and wording for health claims.

Insoluble fiber The type of fiber found in foods that add bulk to the stools and helps food pass more quickly through the stomach and intestines. It is found in wheat bran, vegetables, and whole grains.

Negligible source There are rules in food labeling that allow for rounding down to zero, or to other low values that reflect the food contains an insignificant amount of a nutrient.

Nutrient content claim Statements that describe the relative amount of nutrients in a product, i.e., 'low in,' 'reduced,' 'free,' 'good source,' 'excellent source.' There are regulatory requirements surrounding use of such terms.

Principal display panel The part of the food label that is used to declare the contents of the product for retail sale.

Qualified health claims Are allowed for specific nutrients and health conditions. They are granted based on petition to FDA and are permitted for use accompanied by significant and specific disclaimers.

Significant Scientific Agreement claims The most robust category for health claims that is held for statements that reflect agreement among credible experts that a nutrient has a positive health effect on the body. There is an evidence-based review and assessment by Food and Drug Administration (FDA) that health claim statements meet such a standard.

Soluble fiber The type of fiber in foods that attracts water and turns to gel during digestion. This slows digestion. Soluble fiber is found in oat bran, barley, nuts, seeds, beans, lentils, peas, and some fruits and vegetables. It is also found in psyllium, a common fiber supplement.

Structure/function claims Claims may be made that reflect how a nutrient affects the structure or function of the body. Regulations dictate specific rules and wording for health claims.

Introduction

Food label is the primary means for communicating with a consumer about a product. The label is highly regulated in the United States and in most parts of the World. Most countries have been updating their food labeling regulations in the past years to better reflect the global regulatory environment. It is regulated to ensure that the label contains all critical information and that it is accurate. The label not only is a means of communicating the contents of a container to a consumer but can also provide critical information to a food allergic individual. The nutrition information contained in the label conveys data on calories and key macro- and micronutrients that can help consumers to prevent obesity and ensure adequate intake of nutrients commonly underconsumed. The food label is where food policy meets the road and becomes personal to a consumer.

Food labels are used to attract customers as much as to inform them the contents of the product. Food labels are effective tools for marketing, but the manufacturer has the responsibility to ensure that the food label is accurate and in compliance to all applicable regulations and that it is truthful and not misleading. The label must present an accurate description of the contents, so that consumers are not deceived about the product. The criteria for labeling in the United States are well described; the measures by which to evaluate truthfulness are not subjective and, in fact, food labeling is quite simple – as long as one knows the rules.

The following information presents the requirements for labeling food in the United States. General food labeling requirements are presented for specific countries representing other regions of the World, including Australia, Brazil, China, Chile, Costa Rica, European Union (EU), India, and Japan. However, this article is not a complete guide to food labeling around the world and specific information should be obtained for food labeling in any given country outside the United States. This article provides specific information about labeling for food products intended for distribution in the United States.

General Food Labeling Requirements

Regulations determine when a product must be labeled and what information must be included. For most food products, there is a requirement for a principal display panel (PDP) and an information panel. The name of the food must be stated that is compliant with any applicable standard of identity. The manufacturer name and address must be given so that a consumer can contact the manufacturer with questions, complaints, and even compliments. The net weight for the product must be listed on the front panel. Nutrition labeling, ingredients, and allergens must be listed on the information panel. Where applicable, cooking instructions and other safe food handling instructions must be presented, which should be sufficient to ensure consumer food safety. Optional information includes a variety of possibilities for health claims and for promoting what is not in the product, for example, preservatives, genetically modified ingredients, *trans* fat, or artificial colors. Although this information is

optional for a manufacturer, there are robust rules that must be followed.

More complex than the label itself is determining when a product must be labeled with a full declaration of ingredients or nutrition information. Packages sold in multipacks or single-serve items and small packages are provided with special rules.

The Federal Agencies That Regulate Food Labels and Their Statutory Authority

In the United States, meat, poultry, and egg products are regulated by the Food Safety and Inspection Service (FSIS); all other food products are regulated by the Food and Drug Administration (FDA). The Federal agencies that have jurisdiction over these products have been granted authority through several principal statutes; these include the Federal Meat Inspection Act, the Poultry Products Inspection Act, the Egg Products Inspection Act, the Agricultural Marketing Act, the Federal Food, Drug, and Cosmetic Act (FFD&CA), and the Fair Packaging and Labeling Act. Additionally, the Federal Trade Commission (FTC) operates under the FTC Act (FTCA) to regulate advertising, an extension of labeling, and prohibits false and misleading advertising.

There are key similarities and differences in the approaches that the FSIS and the FDA take for regulating food labels. It is critical to understand which Federal agency has authority for the product; the determination of jurisdiction is referred to as 'amenability.' Amenability is based on the formulation of the product, as opposed to the final product. The food product is not amenable to FSIS regulations if it contains (1) 3% of less raw meat or less than 2% cooked meat, or (2) less than 2% cooked poultry meat; less than 10% cooked poultry skins, giblet, or fat, separately; and less than 10% of cooked poultry skins, giblet, fat, or meat in combination provided that the poultry ingredients were prepared under domestic or foreign inspection and the product is not represented as a poultry product (USDA, 2005b). Although the FSIS has installed this definition formally only for poultry products, they have extended it historically to determine amenability for meat products as well. The FSIS has also exempted specific foods, for example, bagel dogs, pork and beans, and gravy mixes. Other exemptions include product included in institutional pack and used as soup bases and flavorings that contain less than 15% of cooked poultry meat. Thus, bouillon cubes, poultry broths, gravies, sauces, and flavorings are also exempt from the FSIS (9 CFR Section 381.15(c)) and are regulated by the FDA. The FSIS has authority to exempt items with appropriate rulemaking procedures, so the list of foods exempted is subject to change.

The FSIS was granted authority to include catfish as an amenable species under the Food, Conservation, and Energy Act of 2008. The FSIS published a proposed rule mandating continuous inspection of catfish in 2011. However, in May 2012, the Government Accountability Office published their report on Seafood Safety, stating that the United States Department of Agriculture (USDA) should not be granted responsibility for catfish and that authority should remain with the FDA GAO, 2011. Reasons included inefficient use resources and duplication of efforts and that the new authority for the FDA granted under the Food Safety Modernization Act (FSMA) of 2010 provides the FDA with ample capacity to continue their regulation of catfish and therefore labeling of catfish products.

The authority of the FTC is also understood, although the food label is not defined as 'advertising.' The FTCA states that the FTC shall prohibit the false advertisement of 'foods, drugs, and cosmetics' (15 USC Section 52) and prevent 'unfair or deceptive acts of practices in or affecting commerce' (15 USC Section 45(a)(1)). This is broad authority that the FTC utilizes to take action on false and misleading labeling of food products ('Fresh Grown Preserve Corp v. FTC' 125 F.2d917 (2d Cir. 1942). An advertising claim, including claims on labels, may be deemed false or misleading if it is not adequately sustained in accordance with FTC guidelines. The courts have upheld FTC's authority to proceed with action against false labeling of food products. One of the most interesting of food label claim cases involves FTC's pursuit of POM Wonderful™. The FTC has battled POM Wonderful LLC, makers of a popular pomegranate juice, for more than 3 years to date, stating that the brand makes misleading claims about the health benefits of the beverage. They have held the company to a standard for substantiation of claims of two randomized, well-controlled, human clinical trials, which the FTC proclaims that they lack. The makers of the product believe that this is an excessive standard that applies only to pharmaceutical products and have continued to battle the FTC in legal disputes. The case continues at this date but has clearly galvanized the existence of FTC's legal authority over food labeling and advertising (FTC, 2013).

When Packages Must Be Labeled

The requirement is clear that all foods must be labeled. However, the complexity of food packaging and marketing practices require further clarification of how foods are labeled. First, it is important to note that 'labeling' extends beyond the food package and includes point-of-purchase materials, promotional brochures, and shelf information. Next, the label required depends on the format the product leaves the facility or inspected establishment for FSIS-regulated products. For example, meat products may be wrapped in a protective covering that is exempt from marking and labeling requirements if placed within a package for shipping that meets all mandatory labeling requirements. Additionally, meat products may be shipped from one inspected establishment to another for further processing without each package being labeled, provided that the immediate containers with protective coverings are packaged in shipping container that is labeled 'Packed for Institutional Use Only.' The unlabeled products may not be removed for further distribution or sold at retail (9 CFR Sections 301.2 and 381.1). Unprocessed meats may be removed from the shipping container for resale and distribution to retailers, including restaurant, provided that the product bears a legible official mark of USDA inspection and the establishment number.

Whole bird or cut poultry may be distributed in protective coverings and further sold to retailers without marking on the packages, provided that the shipping container bears all

required labeling features (i.e., product name, handling statement, mark of inspection, establishment number, net weight, ingredients, signature line, nutrition facts, and safe handling instructions, if needed).

Given the wide variations in mandatory labeling for meat and poultry products according to USDA regulation, it is prudent to refer to the regulation in 21 CFR for specific requirements for labeling the type and package of meat or poultry product intended.

Prior Approval Required for Meat and Poultry Products

Food labels on FDA-regulated products and FSIS-regulated products must comply with all requirements, but meat and poultry product labels require that the FSIS approve their content and context before marketing. This 'prior approval' requirement for the FSIS has evolved over the year, reflecting the size of the industry, the number of products in the marketplace with frequent changes to their labels, and finite resources of the Agency. Previously, each label on a meat or poultry product was submitted to the Agency for approval. Modifications to labels required resubmission and approval. Only minor modifications were able to be approved by local inspectors in the establishment. This need gave rise to a new industry of 'label expeditors' who act as intermediaries between companies needing rapid label approvals to get products into the marketplace and resource-constrained federal label reviewers. Regulations were changed to allow the current practice of sketch approval based on submission of a label application to the FSIS (Sketch labeling). A sketch-approved label may be modified by the company as long as they follow the requirements contained in the regulation. There is also provision for generic labeling that does not require submission for approval by the agency. These provisions have streamlined the label review process for the FSIS and provided needed speed-to-market capability for the industry.

Mandatory Requirements of the Food Label

There are six required elements of the label for FDA-regulated product and eight for FSIS-regulated products. For FDA products, the PDP must include the name of the product or identity and statement of net quantity. Other information is required to be on the Information Panel which is placed to the right of the PDP. The Information Panel states the name and address of the manufacturer, packer, or distributor; the ingredient statement, the nutrition fact panel; and allergen statement. FSIS-regulated products require the product name, inspection legend and establishment number, handling statement, net weight statement, ingredient statement, address line, nutrition facts, and safe handling instructions. The rationale for the difference between the two regulatory agencies is explained by the nature of the foods they regulate. Meat and poultry products are generally highly perishable and handling instructions may be needed to ensure food safety; whereas, FDA-regulated products may be shelf stable and less prone to bacterial growth but may present an array of allergen risks that need to be communicated to consumers. This statement is a generalization of the foods the respective agencies regulate, but it helps to put the agencies in context of the products they oversee in order to explain the myriad of differences between their regulations.

Placement and prominence of the required elements are specified in regulations. The type size must be prominent and conspicuous and easy to read. The information must be in such terms as "to render it likely to be read and understood by the ordinary individual under customary conditions of purchase and use" (9 CFR Section 317.2(b)).

Principal Display Panel

For the FSIS and the FDA, the PDP is the part of the label most likely to be displayed, presented, shown, or examined under customary conditions to the consumer (9 CFR Section 317.2 (d); 21 CFR 101.1). For FSIS-regulated products, the PDP must contain the name of the product (compliant with standards of identity, if applicable), net quantity of contents, the official inspection legend, number of the official establishment, and if necessary, handling information (e.g., Keep Refrigerated). For FDA-regulated products, it must contain the name of the product (compliant with standards of identity, if applicable) and net quantity of contents. Similar handling information is also typically found on the PDP, if applicable (e.g., Keep Frozen).

Size of the PDP is also regulated and the regulations are similar for the two agencies. For rectangular packaging, the PDP is one entire side. For a cylindrical container, the PDP is an area 40% of the product at the height of the container times the circumference of the container, the width of which is one-third of the circumference, and the height of which is as high as the container. For any other configuration of container, the PDP is 40% of the total surface area.

Type size is also regulated. All information appearing on the PDP shall appear prominently and conspicuously, but in no case may the letters or numbers be less than one-sixteenth inch in height (9 CFR Section 317.2 (m) meat; 9 CFR Section 381.116 (c) poultry; 21 CFR Section 101.1 (FDA)).

Information Panel

The Information Panel is found to the right of and immediately contiguous with the PDP. It must contain the ingredient statement, name and address of the manufacturer or distributor, and nutrition labeling, if required. Safe handling instructions, including cooking/preparation instructions, may be placed anywhere on the label.

Type size is also regulated. All information appearing on the information panel shall appear prominently and conspicuously, but in no case may the letters or numbers be less than one-sixteenth inch in height. Type size is regulated (9 CCFR Section 317.2 (m) (meat); 9 CFR Section 381.116 (c) (poultry); 21 CFR Section 101.2 (FDA)).

Product Name, Placement, and Prominence

The name of the product included on the PDP must comply with naming requirements in order to accurately convey to

consumers the contents of the container. The name must be consistent with a standard of identity or be a common or usual name, or a truthful description of the product.

Standards of identity are listed in regulation. They are found as follows: for meat, see 9 CFR Section 319; for poultry, see 9 CFR Section 381.155–381.174; and for FDA products, see 21 CFR Sections 130–169. Standards have also been created by other authoritative bodies, including the Codex Alimentarius Commission. If they exist and the product complies with the standard, they must be used. Standards of identity are found for ice cream, cheese, bacon, hot dogs, and much more.

For products with no standard of identity or common name, descriptive names may be used. A descriptive name describes the food: its character, manner of preparation, and ingredients; for example, chopped, sliced, smoked, grilled, with pimento, and rosemary infused.

The standards control components and ingredients in the product and were created to prevent imitation products from being presented as real. For example, the standards control fat that may have at one time been a driver of economic validity for the product but today may be undesired from a consumer preference perspective. Both the FDA and the FSIS have adopted provisions to allow companies deviating from standards of identity to avoid labeling products as 'imitation.' Products must be labeled as 'imitation' if they are nutritionally inferior to standardized products. This means, technically, that a food which is reduced from standard in fat, salt, saturated fat, or cholesterol must be labeled as 'imitation.' However, these modifications may be made to comply with consumer preferences and companies long ago sought the agencies' considerations that foods be labeled appropriately but without the stigma that 'imitation' confers. Both agencies enable qualifying products to be labeled with the standardized name, provided that other information is included that describes the components of the product for the consumer. These labels are descriptive names, which list the food, bacon or cheese, for example, along with other ingredients, for example, water, tenderizing solution, 2% milk – whatever distinguishes the food product from the standardized product. Reduced fat versions of standardized products may be labeled 'Reduced Fat' or 'Low Sodium,' provided that regulatory requirements for use of the term are satisfied. In this way, the regulatory agencies opened the way for food companies and marketers to satisfy consumers' desires for a wide variety of foods that meet their nutrition needs and lifestyle preferences while still complying with the key regulatory requirement to provide truthful and not misleading information about products to consumers.

Naming configurations may also note geographic significance to consumers. Different regions of the world have specific character, for example, Tuscan, Southwest, the Middle East. When these terms are used that do not refer to the region where the product was made, they may be used in conjunction with the term 'style' or 'type,' for example, Tuscan-style Marinara Sauce or Southwestern-style Grilled Chicken. Poultry products long had strict standards regarding geographic origin, but the FSIS has installed policies that allow more flexibility today. However, if a duck product is labeled 'Long Island Duck' and not 'Long Island-style Duck,' it should be understood that the duck was raised on Long Island.

Some geographic terms have been deemed by the FSIS to no longer have geographic significance and are now in general use as trade names. These terms do not require use of 'type' or 'style.' For example, Vienna Sausages are small hot dogs that generally come in cans and Italian Sausage is a spicy sausage and may be mild or hot, but it is now commonly known as 'Italian Sausage' and is permitted without additional qualifiers.

Country of Origin Labeling

USDA's Agriculture Marketing Service installed regulations for country of origin labeling (COOL) in March 2009 and is responsible for the implementation, administration, and enforcement of COOL regulations. Under COOL, retailers must provide their customers with information about the origin of various food products, including meats, poultry, raw fruits and vegetables, and fish and shellfish. Mandatory COOL requirements help consumers to make informed purchasing decisions about the food they buy.

Imported meats, poultry, raw fruits and vegetables, and fish and shellfish must bear the name of the country of origin, preceded by the words 'Product of' (9 CFR Section 327.14). The country of origin statement must appear on the immediate container for the product and must be immediately under the name of the product. It must also be located next to the name of the product on any outside, consumer-facing packaging. In March 2013, the USDA proposed to add to the COOL requirements for muscle cuts of meat, further requiring that there be separate designations for geographic locations where the animal was born, raised, and slaughtered in order to provide full information to consumers. The proposal also will eliminate the allowance for commingled muscle cuts, making the US COOL requirements more parallel with those of Europe.

The FDA does not require COOL for imported foods; however, it is a requirement of the US Customs and Border Protection (CBP) as authorized by the Tariff Act of 1930 and CPB regulations (19 CFR Part 134). Repackers are required by CBP to mark containers of repackaged imports with the English name of the country of origin. In the event that further reprocessing or material added to the article in another country results in a 'substantial transformation' of the product, the other country becomes the country of origin within the meaning of CBP's labeling requirements, 19 CFR 134.1(b) and 134.11. As a result, there have been seizure actions and other regulatory follow-up involving imported shrimp that was peeled, deveined, and repacked in the United States and labeled as a product of the US FDA-received congressional, industry, and field inquiries regarding FDA's jurisdiction and policy on COOL for this product. However, CBP and the FDA have sustained that peeling, deveining, and repacking is not a 'substantial transformation' of the product, sufficient to permit the shrimp to be declared as a product of the United States. The threshold for 'substantial transformation' includes that the product loses its primary character. For example, an imported product, such as shrimp, is peeled and deveined or otherwise preserved after importation but is still identified and sold as 'shrimp.' If labeled as a 'product of the USA,' it would be misbranded because the labeling would be false and

misleading within the meaning of section 403(a)(1) of the FFD&CA. However, if an imported product, such as shrimp, is peeled, deveined, and incorporated into a shrimp dish, such as 'Shrimp Quiche,' the product is no longer identifiable as shrimp but as 'Quiche.' The quiche is a product of the USA. Therefore, labeling it as 'Product of the USA' would not be a violation of the FFD&CA. It is not sufficient to declare a product to be 'imported by' or 'distributed by' without also declaring its country of origin. An imported product, such as shrimp, which is peeled and deveined, is labeled as 'Imported by' or 'Distributed by' a firm in the USA. Such labeling would not violate the FFD&CA, but it would not meet the CBP requirement for COOL. The product would also have to be clearly identified as to country of origin.

The FDA's policy regarding false or misleading COOL is to defer to CBP. Such labeling is also a violation of the Tariff Act of 1930, which is enforced by CBP, and CBP can generally deal with this problem more efficiently than FDA.

Net Quantity Declaration

Net quantity declarations enable consumers to make value comparisons for similar products at point of purchase. All labels sold at retail must state the accurate quantity of the package contents by avoirdupois weight, liquid measure, or numerical count (9 CFR Section 317.2(h)). Generally, if the food is solid, semisolid, or viscous, it should be expressed in fluid measure (e.g., fl oz) (21 CFR Section 101.105(a)). The net quantity statement is placed on the PDP as a distinct item in the bottom 30% of the panel, in lines generally parallel with the base of the container (21 CFR 101.105(e) and (f); 9 CFR Section 317.2(h)).

FSIS-regulated products do not require metric measures be listed, but FDA regulations require that net contents be labeled in both metric (grams, kilograms, milliliters, and liters) and US Customary System (ounces, pounds, and fluid ounces) terms. The metric statement may be placed either before or after the US Customary statement, or above or below it. Each of the following examples is correct (21 CFR Section 101.105):

Net weight 1 lb 8 oz (680 g)
Net wt 1 lb 8 oz 680 g
500 ml (1 pt 0.9 fl oz)
Net contents 1 gal (3.79 L).

The size of the net quantity declaration is also regulated and is dependent on the area of the PDP. The declaration must be conspicuous and easily legible boldface print or type and lettering may be no more than three times high as it is wide (9 CFR Section 317.2(h)). The FSIS and the FDA share minimum type size requirements. The area of the panel is calculated as follows: for a rectangle or square, the area is the height multiplied by the width (both in inches or both in centimeters); for a cylinder, use 40% of the product of the height by the circumference (21 CFR Section 101.1).

For the net quantity statements, the minimum type size is the smallest type size that is permitted based on the space available for labeling on the PDP. Determine the height of the type by measuring the height of the lower case letter 'o' or its equivalent when mixed upper and lower case letters are used, or the height of the upper case letters when only upper case letters are used (21 CFR Section 101.105(h) and (i)).

For the net quantity statements, the minimum type size is the smallest type size that is permitted based on the space available for labeling on the PDP. Determine the height of the type by measuring the height of the lower case letter 'o' or its equivalent when mixed upper and lower case letters are used, or the height of the upper case letters when only upper case letters are used (21 CFR Section 101.105(h) and (i); 21 USC Section 671(meat)).

Minimum Type Size	*Area of PDP*
1/16 in. (1.6 mm)	5 sq. in. (32 sq. cm.) or less
1/8 in. (3.2 mm)	More than 5 sq. in. (32 sq. cm.) but not more than 25 sq. in. (161 sq. cm.)
3/16 in. (4.8 mm)	More than 25 sq. in. (161 sq. cm.) but not more than 100 sq. in. (645 sq. cm.)
1/4 in. (6.4 mm)	More than 100 sq. in. (645 sq. cm.) but not more than 400 sq. in. (2580 sq. cm.)
1/2 in. (12.7 mm)	More than 400 sq. in. (2580 sq. cm.)

The FSIS exempts net weight labeling for small packages of less than 0.5 ounces that are individually wrapped and labeled. However, their shipping container must declare the accurate net quantity of the container and must not be otherwise false or misleading (9 CFR Section 317.2(h)(9)(ii)). The FDA provides exemptions for small packages provided that they display the following or an equivalent representation: 'Not labeled for individual sale.'

There are provisions for reasonable variance from declared weight caused by loss or gain of moisture during the course of distribution or storage, provided that the deviation is unavoidable given good distribution and good manufacturing practices and that the product is not rendered misbranded (9 CFR Section 317.2(h)).

Ingredients

Ingredient labeling carries with it specific requirements that dictate knowledge of the product formulation and functionality of ingredients. All ingredients must be declared by their common or usual names on the label in descending order of prominence by weight (USDA, 2005a; 21 CFR Section 101.4). The descending order of predominance requirements do not apply to ingredients present in amounts of 2% or less by weight when a listing of these ingredients is placed at the end of the ingredient statement following an appropriate quantifying statement, for example, "Contains _ percent or less of ___" or "Less than _ percent of ___." The blank percentage within the quantifying statement shall be filled in with a threshold level of 2%, or, if desired, 1.5%, 1.0%, or 0.5%, as appropriate. No ingredient to which the quantifying phrase applies may be present in an amount greater than the stated threshold.

Ingredients that are combinations of subingredients may be listed by an established common or usual name of the ingredient followed by a parenthetical listing of all ingredients contained therein in descending order of predominance except that, if the ingredient is a food subject to a definition and

standard of identity that has specific labeling provisions for optional ingredients, listings of subingredients must not list the ingredient itself.

Ingredients are identified by functionality, for example, leaving agents (baking powder, monocalcium phosphate, and calcium carbonate), firming agents (calcium salts), yeast nutrients (calcium sulfate and ammonium phosphate), and dough conditioners (L-cysteine and ammonium sulfate).

Sugar is an interesting ingredient for labeling. Some manufacturers would like to present multiple sources of sweetness as 'sugar,' whereas others want to conceal high levels of sugar in their products but presenting sweeteners by their multiple names. For the purposes of FDA's labeling, sugar is derived from sugarcane or sugar beets, and all other sources of sweetness must be accurately labeled (21 CFR Section 101.4(20)).

The term 'flavorings' is used to designate natural spices and natural spice extracts. Nonnatural flavors must be represented as 'artificial flavors.' Only spices, spice extracts, essential oils, and oleoresins may be presented as 'natural flavor,' 'natural flavoring,' 'flavor,' or 'flavoring' (21 CFR Sections 182.10 and 184). Hydrolyzed ingredients, such as hydrolyzed proteins or autolyzed yeast, may not be presented as a 'flavor' and must be separately labeled. The FDA declares that an artificial flavoring means any substance, the function of which is to impart flavor, which is not derived from a spice, fruit or fruit juice, vegetable or vegetable juice, edible yeast, herb, bark, bud, root, leaf or similar plant material, meat, fish, poultry, eggs, dairy products, or fermentation products thereof (21 CFR Section 101.22(a)(1)).

The use of artificial smoke for flavor and artificial colors must not only be identified in the ingredient statement but must also be on the product label next to the product name.

Chemical preservatives must also be declared on the label. The ingredient must be labeled by its chemical name and the purpose of its use (9 CFR Section 381.120). The FDA declares chemical preservative means any chemical that, when added to food, tends to prevent or retard deterioration thereof but does not include common salt, sugars, vinegars, spices, or oils extracted from spices, substances added to food by direct exposure thereof to wood smoke, or chemicals applied for their insecticidal or herbicidal properties (21 CFR Section 101.22(a)(5)).

Allergens

Significant legislation was passed in the United States in 2004 supporting allergen labeling. The Food Allergen Labeling and Consumer Protection Act (FALCPA) amended the FFD&CA to reinforce the criticality of consistently and clearly labeling food allergens. The FALCPA requires that any ingredient containing protein derived from one of the 'Big Eight' allergen food and food groups must be labeled: milk, wheat, soy, peanut, tree nut, fish, crustacean shellfish, and egg. The allergen must be clearly identified in plain English on the information panel of food labels. These eight foods and food groups account for 90% of all food allergies. The FALCPA also requires the type of tree nut (e.g., almonds, pecans, and walnuts), the type of fish (e.g., bass, flounder, and cod), and the type of Crustacean shellfish (e.g., crab, lobster, and shrimp) to be declared.

The FSIS is not included in the authority granted by the FALCPA, but the FSIS supports voluntary statements on labels to inform consumers who are allergic of sensitive food ingredients. They encourage clear listing of the eight major allergens and other specific ingredients, including monosodium glutamate, sulfites, lactose, and Yellow #5 (tartrazine). They support similar language as required by the FALCPA, i.e., use of the words 'Contains:' before listing allergens and in providing the specific source of the specific ingredient in a parenthetical statement (e.g., 'casein (from milk)').

Use of terms that refer to the manufacturing environment, for example, 'Made in a plant that also produces soy, peanuts, and tree nuts,' is permitted, but it is not without controversy. Manufacturers may also use the term 'May Contain' in reference to allergens that they fail to control in the manufacturing, storage, or distribution process. The application of good manufacturing practices and effective sanitation programs should preclude the use of such phrases and they are regarded by some consumer groups inadequate and ineffective ways to protect food allergic and sensitive individuals. Food manufacturers should take all necessary steps to control allergens, prevent cross-contamination in the food manufacturing environment, and provide consumers with reliable information that they can use. Use of 'catch all' phrases is not useful to consumers, because the intent is to leave the consumer with the responsibility to decide whether to take a risk and consume the food or avoid it altogether. These terms should not be used to mislead consumers.

Other allergenic foods (e.g., sesame) are not required to be declared in accordance with the FALCPA. Canada includes sesame, mustard, and sulfites in their list of major allergens declared on labels and classifies fish and shellfish together as 'seafood.' The EU lists cereals containing gluten, crustaceans, mollusks, eggs, fish, peanuts, nuts, soybeans, milk, celery, mustard, sesame, lupin, and sulfur dioxide at levels above 10 mg/kg, or 10 mg/l, expressed as sulfur dioxide. The EU also updated their 2003 and 2006 food allergen labeling requirements in 2011, with the Food Information for Consumers Regulation 1169/2011. The new regulation is built on current allergen labeling provisions for prepacked foods and introduces a new requirement for allergen information to be provided for foods sold nonpacked or prepacked for direct sale. It also requires that a label state any use of milk, rather than the more nebulous terms of casein, sodium caseinate, lactoglobulin, or lactalbumin that could be used alone previously. The new regulation will be in effect from December 2014.

A food product may be subject to recall if it contains a major food allergen as an ingredient not declared on the food label in accordance with FALCPA requirements. Penalties for noncompliance under the FALCPA include civil sanctions, criminal penalties, and the potential for the seizure of products or for a request for a recall by the manufacturer or distributor. Nearly half of all recalls (40%) in the United States are due to undeclared food allergens (Expert Recall 2012). The FDA will have increased ability to ensure that food allergen management programs are in place with implementation of the FSMA, which requires hazard analysis and installation of preventative controls, including allergen programs.

Address

The information panel must also include the name or trade name and place of business for the manufacturer, packer, or distributor for the food product. If the name of the distributor is listed, it may be preceded by the term 'Prepared For' or 'Distributed By.' If the business is listed publically and is available in a telephone or city directory, then the listing of place of business may contain only the city, state, and postal zip code. If not publically available, a street address must be given. The purpose is to enable a customer to contact someone with regard to the food and information must be made accessible to consumers.

Handling Statements

Products that must be maintained frozen or refrigerated in order to protect their perishable state must be labeled prominently on the PDP with special handling information, including 'Keep Frozen,' 'Keep Refrigerated,' or 'Perishable – Keep Refrigerated or Frozen' (9 CFR Section 317.2(k) (meat); 9 CFR Section 381.125(a) (poultry)). Other special handling and warning statements that must be included comprise protein foods used for weight loss diets, foods containing psyllium husks, unpasteurized juices, and shell eggs (21 CFR Section 101.17 (FDA)).

Safe handling instructions are also required for meat and poultry products that are raw or partially cooked (i.e., not ready to eat) and sold to the retail market. (9 CFR Section 317.2(l) (meat); 9 CFR Section 381.125(b) (poultry)) They should not be used for ready-to-eat food products and products intended for further processing are exempt. Safe handling instruction tells the consumer how to safely prepare the food to eat. Instructions include 'Cook Thoroughly' and must appear in lettering no less that 1/16 in. in height and must be placed prominently on the label such that "it is likely to be read and understood under customary conditions of purchase and use."

Failure to utilize the safe handling instructions effectively is a liability to a manufacturer. In the 2007 case involving ConAgra's Banquet line of pot pies, chicken pot pies were identified to contain *Salmonella* and eventually 401 illnesses were reported in 41 states. The company acknowledged that chicken pies were involved and initially refused to recall turkey pot pies, asking consumers to cook the products thoroughly before eating. Eventually, they recalled all pot pies and stated that their cooking instructions were 'unclear,' leaving too much discretion to consumers to understand the performance of their particular microwave oven. However, the case had long lasting effects on the ConAgra brand with six civil lawsuits being settled.

Nutrition Labeling

The Nutrition Labeling and Education Act (NLEA) of 1990 brought sweeping changes to the way food products are labeled in the United States and successfully impacted the development of similar nutrition labeling rules in other countries. Both the FDA and the USDA adopted regulations implementing the law that went into effect in 1994. The law authorized the FDA to require nutrition information labeling on packaged foods and to regulate nutrient content and health claims for all foods.

The objectives of the NLEA were to clear up consumer confusion about food label information, help consumers to make more healthful food choices, and encourage food manufacturers to make to sell more healthy products. Nutrients were required to be listed on a Nutrition Fact Panel, including calories, calories from fat, saturated fat, and sugars; other nutrients could be made available, and the nutrient information per serving had to be placed in the context of a daily diet. In 2003, regulation for labeling of *trans* fat was added.

A question that has been raised for two decades is whether nutrition labeling impacts food choices. It is agreed that in order to impact health, consumers must use the labels and understand what they mean. According to the 2008 Health and Diet Survey conducted by the FDA (FDA, 2008), 54% of consumers reported often using the food label when purchasing a food item for the first time. There are indications of increased use of food label information in the years immediately after the implementation of NLEA. In the 1990 Health and Diet Survey, 30% of consumers said that they changed their minds about buying a food product because they read the nutrition label. By the end of 1995, approximately 1 year after the food labeling legislation went into effect, 48% reported using the label to drive purchase decision (Levy and Derby, 1996). Over the years, although this number has not increased, it has remained stable, with 49% of respondents in the 2008 survey reporting changing their minds about purchasing a product based on reading the nutrition label.

The matter of changing food behavior is a greater question than one of providing information. Knowledge of nutrient content may or may not alter behavior, because dietary practices and food consumption patterns are influenced by a myriad of factors. However, behavioral change may not be easily effected without awareness, and making consumers aware of nutrient content of foods with clear and honest representation of claims was the intent of the 1994 NLEA.

Products to be Nutrition Labeled

Nutrition labeling is required for all FSIS-regulated products, including major cuts of raw meat and poultry, and ground products. The original regulations were amended in 2012 to include single-ingredient, major cuts of raw meat and poultry. Exemptions exist for small businesses, small packages (less than 0.5 ounce or less than 12 sq. inches), and for custom-ground products at retail. Nutrition labeling is required for all FDA-regulated prepackaged food products.

Nutrition Fact Panel – Required Elements

The following information must be contained on the Nutrition Fact Panel ('the Panel'). The format, order, and type size is specified (9 CFR Section 317.309(d) (meat); 21 CFR Section 101.9).

Serving size

The term serving or serving size means the amount of food customarily consumed per eating occasion by persons 4 years of age or older. It is expressed in a common household measure that is appropriate to the food. The serving size declared on a product label is determined from the 'Reference Amounts Customarily Consumed Per Eating Occasion' (reference amounts) that appear in regulation (21 CFR 101.12(b)).

For products sold in discrete units (e.g., muffins, sliced products, such as sliced bread, or individually packaged products within a multiserving package) and for products which consist of two or more foods packaged and presented to be consumed together where the ingredient represented as the main ingredient is in discrete units (e.g., pancakes and syrup), the serving size is declared as follows:

1. If a unit weighs 50% or less of the reference amount, the serving size is the number of whole units that most closely approximates the reference amount for the product category;
2. If a unit weighs more than 50%, but less than 67% of the reference amount, the manufacturer may declare one unit or two units as the serving size;
3. If a unit weighs 67% or more, but less than 200% of the reference amount, the serving size is one unit;
4. If a unit weighs 200% or more of the reference amount, the manufacturer may declare one unit as the serving size if the whole unit can reasonably be consumed at a single eating occasion.
5. For products that have reference amounts of 100 g or ml or larger and are individual units within a multiserving package, if a unit contains more than 150% but less than 200% of the reference amount, the manufacturer may decide whether to declare the individual unit as 1 or 2 servings.

Calories: 'calories, total,' 'total calories,' or 'calories'

A statement of the caloric content per serving, expressed to the nearest 5-calorie increment up to and including 50 cal, and 10-calorie increment above 50 cal, except that amounts to less than 5 cal may be expressed as zero. Energy content per serving may also be expressed in kilojoule units, added in parentheses immediately following the statement of the caloric content.

Calories from fat

A statement of the caloric content derived from total fat in a serving, expressed to the nearest 5-calorie increment, up to and including 50 cal, and the nearest 10-calorie increment above 50 cal, except that label declaration of 'calories from fat' is not required on products that contain less than 0.5 g of fat in a serving and amounts to less than 5 cal may be expressed as zero. This statement shall be declared as provided in paragraph (d)(5) of this section. If 'Calories from fat' is not required and, as a result, not declared, the statement "Not a significant source of calories from fat" shall be placed at the bottom of the table of nutrient values in the same type size.

Calories from saturated fat (voluntary)

A statement of the caloric content derived from saturated fat in a serving may be declared voluntarily, expressed to the nearest 5-calorie increment, up to and including 50 cal, and the nearest 10-calorie increment above 50 cal, except that amounts to less than 5 cal may be expressed as zero. If present, this statement is indented under the statement of calories from fat.

Fat: 'fat, total' or 'total fat'

A statement of the number of grams of total fat in a serving defined as total lipid fatty acids and expressed as triglycerides. Amounts shall be expressed to the nearest 0.5 (1/2) g increment below 5 g and to the nearest gram increment above 5 g. If the serving contains less than 0.5 g, the content shall be expressed as zero. Daily Reference Value (DRV) used for calculating %DV is 65 g.

Saturated fat: 'saturated fat' or 'saturated'

A statement of the number of grams of saturated fat in a serving defined as the sum of all fatty acids containing no double bonds, except that label declaration of saturated fat content information is not required for products that contain less than 0.5 g of total fat in a serving if no claims are made about fat, fatty acid, or cholesterol content, and if 'calories from saturated fat' is not declared. If a statement of the saturated fat content is not required and, as a result, not declared, the statement "Not a significant source of saturated fat" shall be placed at the bottom of the table of nutrient values. Saturated fat content is indented and expressed as grams per serving to the nearest 0.5 g (1/2) gram increment below 5 g and to the nearest gram increment above 5 g. If the serving contains less than 0.5 g, the content shall be expressed as zero. DRV used for calculating %DV is 20 g.

Trans *fat: 'trans fat' or 'trans'*

A statement of the number of grams of *trans* fat in a serving, defined as the sum of all unsaturated fatty acids that contain one or more isolated (i.e., nonconjugated) double bonds in a *trans* configuration, except that label declaration of *trans* fat content information is not required for products that contain less than 0.5 g of total fat in a serving if no claims are made about fat, fatty acid, or cholesterol content. The word '*trans*' may be italicized to indicate its Latin origin. *Trans* fat content is indented and expressed as grams per serving to the nearest 0.5 (1/2)-gram increment below 5 g and to the nearest gram increment above 5 g. If the serving contains less than 0.5 g, the content, when declared, shall be expressed as zero. If a statement of the *trans* fat content is not required and, as a result, not declared, the statement "Not a significant source of *trans* fat" shall be placed at the bottom of the table of nutrient values.

Polyunsaturated fat: 'polyunsaturated fat' or 'polyunsaturated' (voluntary)

A statement of the number of grams of polyunsaturated fat in a serving defined as *cis,cis*-methylene-interrupted polyunsaturated fatty acids may be declared voluntarily, except that when monounsaturated fat is declared, or when a claim about fatty acids or cholesterol is made on the label or when a claim for 'fat free' is labeled then declaration of polyunsaturated fat is required. Polyunsaturated fat content is indented and expressed as grams per serving to the nearest 0.5 (1/2) gram increment below 5 g and to the nearest gram increment above

5 g. If the serving contains less than 0.5 g, the content shall be expressed as zero.

Monounsaturated fat: 'monounsaturated fat' or 'monounsaturated' (voluntary)

A statement of the number of grams of monounsaturated fat in a serving defined as *cis*-monounsaturated fatty acids may be declared voluntarily except that when polyunsaturated fat is declared, when a claim about fatty acids or cholesterol is made on the label, or when a claim for 'fat free' is made on the label, then declaration of monounsaturated fat is required. Monounsaturated fat content is indented and expressed as grams per serving to the nearest 0.5 (1/2) g increment below 5 g and to the nearest gram increment above 5 g. If the serving contains less than 0.5 g, the content shall be expressed as zero.

Cholesterol

A statement of the cholesterol content in a serving expressed in milligrams to the nearest 5-milligram increment, except that label declaration of cholesterol information is not required for products that contain less than 2 mg cholesterol in a serving and make no claim about fat, fatty acids, or cholesterol content, or such products may state the cholesterol content as zero. If cholesterol content is not required and, as a result, not declared, the statement "Not a significant source of cholesterol" shall be placed at the bottom of the table of nutrient values in the same type size. If the food contains 2–5 mg of cholesterol per serving, the content may be stated as 'less than 5 mg.' DRV used for calculating %DV is 300 mg.

Sodium

A statement of the number of milligrams of sodium in a specified serving of food expressed as zero when the serving contains less than 5 mg of sodium, to the nearest 5 mg increment when the serving contains 5–140 mg of sodium, and to the nearest 10 mg increment when the serving contains greater than 140 mg. DRV used for calculating %DV is 2400 mg.

Potassium (voluntary)

A statement of the number of milligrams of potassium in a specified serving of food may be declared voluntarily, except that when a claim is made about potassium content, label declaration is required. Potassium content is expressed as zero when the serving contains less than 5 mg of potassium, to the nearest 5 mg increment when the serving contains less than or equal to 140 mg of potassium, and to the nearest 10 mg increment when the serving contains more than 140 mg. DRV used for calculating %DV is 3500 mg.

Carbohydrates: 'carbohydrate, total' or 'total carbohydrate'

A statement of the number of grams of total carbohydrate in a serving expressed to the nearest gram, except that if a serving contains less than 1 g, the statement "Contains less than 1 g" or "less than 1 g" may be used as an alternative, or if the serving contains less than 0.5 g, the content may be expressed as zero. Total carbohydrate content is calculated by subtraction of the sum of the crude protein, total fat, moisture, and ash from the total weight of the food. DRV used for calculating % DV is 300 g.

Dietary fiber

A statement of the number of grams of total dietary fiber in a serving, indented and expressed to the nearest gram, except that if a serving contains less than 1 g, declaration of dietary fiber is not required or, alternatively, the statement "Contains less than 1 g" or "less than 1 g" may be used, and if the serving contains less than 0.5 g, the content may be expressed as zero. If dietary fiber content is not required and as a result, not declared, the statement "Not a significant source of dietary fiber" shall be placed at the bottom of the table of nutrient values in the same type size. DRV used for calculating %DV is 25 g.

Soluble fiber (voluntary)

A statement of the number of grams of soluble dietary fiber in a serving may be declared voluntarily except when a claim is made on the label or in labeling about soluble fiber, label declaration is required. Soluble fiber content shall be indented under dietary fiber and expressed to the nearest gram, except that if a serving contains less than 1 g, the statement "Contains less than 1 g" or "less than 1 g" may be used as an alternative, and if the serving contains less than 0.5 g, the content may be expressed as zero.

Insoluble fiber (voluntary)

A statement of the number of grams of insoluble dietary fiber in a serving may be declared voluntarily except that when a claim is made on the label or in labeling about insoluble fiber, label declaration shall be required. Insoluble fiber content shall be indented under dietary fiber and expressed to the nearest gram except that if a serving contains less than 1 g, the statement "Contains less than 1 g" or "less than 1 g" may be used as an alternative, and if the serving contains less than 0.5 g, the content may be expressed as zero.

Sugars

A statement of the number of grams of sugars in a serving, except that label declaration of sugars content is not required for products that contain less than 1 g of sugars in a serving if no claims are made about sweeteners, sugars, or sugar alcohol content. If a statement of the sugars content is not required and, as a result, not declared, the statement "Not a significant source of sugars" shall be placed at the bottom of the table of nutrient values in the same type size. Sugars shall be defined as the sum of all free mono- and disaccharides (such as glucose, fructose, lactose, and sucrose). Sugars content is indented and expressed to the nearest gram, except that if a serving contains less than 1 g, the statement "Contains less than 1 g" or "less than 1 g" may be used as an alternative, and if the serving contains less than 0.5 g, the content may be expressed as zero.

Sugar alcohol (voluntary)

A statement of the number of grams of sugar alcohols in a serving may be declared voluntarily on the label, except that when a claim is made on the label or in labeling about sugar alcohol or sugars when sugar alcohols are present in the food, sugar alcohol content is declared. For nutrition labeling purposes, sugar alcohols are defined as the sum of saccharide derivatives in which a hydroxyl group replaces a ketone or aldehyde group and whose use in the food is listed by the FDA

(e.g., mannitol or xylitol) or is generally recognized as safe (e.g., sorbitol). In lieu of the term 'sugar alcohol,' the name of the specific sugar alcohol (e.g., 'xylitol') present in the food may be used in the nutrition label, provided that only one sugar alcohol is present in the food. Sugar alcohol content is indented and expressed to the nearest gram, except that if a serving contains less than 1 g, the statement "Contains less than 1 g" or "less than 1 g" may be used as an alternative, and if the serving contains less than 0.5 g, the content may be expressed as zero.

Other carbohydrate (voluntary)

A statement of the number of grams of other carbohydrates may be declared voluntarily. Other carbohydrate is defined as the difference between total carbohydrate and the sum of dietary fiber, sugars, and sugar alcohol, except that if sugar alcohol is not declared (even if present), it shall be defined as the difference between total carbohydrate and the sum of dietary fiber and sugars. Other carbohydrate content is indented and expressed to the nearest gram, except that if a serving contains less than 1 g, the statement "Contains less than 1 g" or "less than 1 g" may be used as an alternative, and if the serving contains less than 0.5 g, the content may be expressed as zero.

Protein

A statement of the number of grams of protein in a serving, expressed to the nearest gram, except that if a serving contains less than 1 g, the statement "Contains less than 1 g" or "less than 1 g" may be used as an alternative, and if the serving contains less than 0.5 g, the content may be expressed as zero.

There are additional qualifiers for labeling protein: When the protein in foods represented or purported to be for adults and children of 4 or more years of age has a protein quality value that is a protein digestibility-corrected amino acid score of less than 20 expressed as a percent, or when the protein in a food represented or purported to be for children greater than 1 but less than 4 years of age has a protein quality value that is a protein digestibility-corrected amino acid score of less than 40 expressed as a percent, either of the following shall be placed adjacent to the declaration of protein content by weight: The statement "not a significant source of protein" or a listing aligned under the column headed 'Percent Daily Value (%DV)' of the corrected amount of protein per serving, calculated as a percentage of the DRV or Reference Daily Intake (RDI), as appropriate, for protein and expressed as percent of DV. When the protein quality in a food as measured by the Protein Efficiency Ratio is less than 40% of the reference standard (casein) for a food represented or purported to be for infants, the statement "not a significant source of protein" shall be placed adjacent to the declaration of protein content. Protein content may be calculated on the basis of the factor of 6.25 times the nitrogen content of the food.

A statement of the corrected amount of protein per serving, calculated as a percentage of the RDI or DRV for protein, as appropriate, and expressed as percent of DV, may be placed on the label, but is required if a protein claim is made for the product or if the product is represented or purported to be for use by infants or children under 4 years of age. (Only allowed for protein of good quality, with protein digestibility-corrected amino acid score of greater than 40%.) The 'corrected amount of protein (gram) per serving' for foods represented or purported for adults and children 1 or more years of age is equal to the actual amount of protein (gram) per serving multiplied by the amino acid score corrected for protein digestibility. If the corrected score is above 1.00, then it shall be set at 1.00.

For the purpose of labeling with a percent of the DRV or RDI, a value of 50 g of protein shall be the DRV for adults and children 4 or more years of age, and the RDI for protein for children less than 4 years of age, infants, pregnant women, and lactating women shall be 16 g, 14 g, 60 g, and 65 g, respectively.

Vitamins and minerals

A statement of the amount per serving of the vitamins and mineral calculated as a percent of the RDI and expressed as percent of DV.

For purposes of declaration of percent of DV, foods represented or purported to be for use by infants, children less than 4 years of age, pregnant women, or lactating women shall use the RDIs that are specified for the intended group. Similarly, the percent of DV based on both the RDI values for pregnant women and for lactating women shall be declared separately on foods represented or purported to be for use by both pregnant and lactating women. When such dual declaration is used on any label, it shall be included in all labeling, and equal prominence shall be given to both values in all such labeling. All other foods shall use the RDI for adults and children 4 or more years of age.

The declaration of vitamins and minerals as a percent of the RDI includes vitamin A, vitamin C, calcium, and iron, in that order, and includes any of the other vitamins and minerals listed below when they are added as a nutrient supplement, or when a claim is made about them. Other vitamins and minerals need not be declared if neither the nutrient nor the component is otherwise referred to on the label or in labeling or advertising.

The percentages for vitamins and minerals are expressed to the nearest 2% increment up to and including the 10% level, the nearest 5% increment above 10% and up to and including the 50% level, and the nearest 10% increment above the 50% level. Amounts of vitamins and minerals present at less than 2% of the RDI are not required to be declared in nutrition labeling but may be declared by a zero or by the use of an asterisk (or other symbol) that refers to another asterisk (or symbol) that is placed at the bottom of the table and that is followed by the statement "Contains less than 2 percent of the Daily Value of this (these) nutrient (nutrients)." If vitamin A, vitamin C, calcium, or iron is present in amounts less than 2% of the RDI and the statement "Not a significant source of _ (listing the vitamins or minerals omitted)" is placed at the bottom of the table of nutrient values, label declaration of the nutrient(s) is not required. Either statement shall be in the same type size as nutrients that are indented.

The following are RDIs used for calculating DV for vitamins and minerals that may be labeled:

Vitamin A, 5000 International Units
Vitamin C, 60 mg
Calcium, 1000 mg
Iron, 18 mg

Vitamin K, 80 μg
Thiamin, 1.5 mg
Riboflavin, 1.7 mg
Niacin, 20 mg
Vitamin B6, 2.0 mg
Folate, 400 μg
Vitamin B12, 6 μg
Biotin, 300 μg
Pantothenic acid, 10 mg
Phosphorus, 1000 mg
Iodine, 150 μg
Magnesium, 400 mg
Zinc, 15 mg
Selenium, 70 μg
Copper, 2.0 mg
Manganese, 2.0 mg
Chromium, 120 μg
Molybdenum, 75 μg
Chloride, 3400 mg

Graphics

Nutrition labels may appear in a variety of formats, depending on the size of the package, the nutritional content of the products, nutrient content claims made, and whether the product is customarily consumed as it is or with additional ingredients, for example, cereal with milk. Formats include full, simplified, and tabular.

Health Claims

A variety of health claims may be made for food products. Generally, these include nutrient content claims, structure/function claims, qualified health claims, and claims with significant scientific agreement (SSA). Nutrient content claims state facts about the presence of positive ingredients (e.g., protein and iron) in a food and are presented in a relative manner, demonstrating that the food is a 'good' or 'excellent' source of the nutrient. Foods may also carry claims that they are reduced in negative nutrients, for example, sodium and saturated fat and may be 'reduced,' 'light,' 'lite,' or 'free.' Structure/function, qualified, and SSA claims may refer to the role of nutrients in supporting health.

Nutrient Content Claims

To label foods with nutrient content statements, the specific language declared in regulations must be used and declared criteria must be met. No other statements regarding nutrient content are allowed in labeling. An express nutrient content claim is any direct statement about the level (or range) of a nutrient in the food (e.g., low sodium) (9 CFR Section 317.313 (b) (meat); 21 CFR Section 101.54). Nutrient content claims are made in relationship to Daily Reference Intake values.

They include:

'High' claims: The terms 'high,' 'rich in,' or 'excellent source of' may be used on the label, provided that the food contains 20% or more of the RDI or the DRV per reference amount customarily consumed. The label must clearly identify the food that is the subject of the claim (e.g., the serving of broccoli in this product is high in vitamin C).

'Good Source' claims. The terms 'good source,' 'contains,' or 'provides' may be used on the label, provided that the food contains 10–19% of the RDI or the DRV per reference amount customarily consumed. The label must clearly identify the food that is the subject of the claim (e.g., the serving of sweet potatoes in this product is a 'good source' of fiber).

'Fiber' claims. If a nutrient content claim is made with respect to the level of dietary fiber, that is, that the product is high in fiber, a good source of fiber, or that the food contains 'more' fiber, and the food is not 'low' in total fat as defined in regulations, then the label must also disclose the level of total fat per labeled serving.

The disclosure must appear in immediate proximity to claim and should be in a type size no less than one-half the size of the claim.

'More' claims. A relative claim using the terms 'more,' 'fortified,' 'enriched,' 'added,' 'extra,' and 'plus' may be used on the label to describe the level of protein, vitamins, minerals, dietary fiber, or potassium, provided that the food contains at least 10% more of the RDI for vitamins or minerals or of the DRV for protein, dietary fiber, or potassium (expressed as a percent of the DV) per reference amount customarily consumed than an appropriate reference food and where the claim is based on a nutrient that has been added to the food.

'High potency' claims. The term 'high potency' may be used on the label to describe individual vitamins or minerals that are present at 100% or more of the RDI per reference amount customarily consumed.

'Light' and 'Lite' Claims

'Light' claims. The terms 'light' or 'lite' may be used on the label provided that:

1. If the food derives 50% or more of its calories from fat, its fat content is reduced by 50% or more per reference amount customarily consumed compared with the reference food; or
2. If the food derives less than 50% of its calories from fat, the number of calories is reduced by at least one-third (33.3%) per reference amount customarily consumed compared with an appropriate reference food.
3. The declaration must appear in immediate proximity to the most prominent such claim (e.g., '1/3 fewer calories and 50% less fat than the regular cheese').
4. A 'light' claim may not be made on a food for which the reference food meets the definition of 'low fat' and 'low calorie.' A product for which the reference food contains 40 cal or less and 3 g fat or less per reference amount customarily consumed may use the term 'light' or 'lite' without further qualification if it is reduced by 50% or more in sodium content compared with the reference food (21 CFR Section 101.56).

Calorie and Sugar Labeling and Claims

Calorie content claims include the terms 'calorie free,' 'free of calories,' 'no calories,' 'zero calories,' 'without calories,' 'trivial

source of calories,' 'negligible source of calories,' or 'dietarily insignificant source of calories' and may be used on the label or in the labeling of foods, provided that the food contains less than 5 cal per reference amount customarily consumed and per labeled serving.

The terms 'low calorie,' 'few calories,' 'contains a small amount of calories,' 'low source of calories,' or 'low in calories' may be used on the label, provided that the food has a reference amount customarily consumed greater than 30 g or greater than 2 tablespoons and does not provide more than 40 cal per reference amount customarily consumed, or the food has a reference amount customarily consumed of 30 g or less or 2 tablespoons or less and does not provide more than 40 cal per reference amount customarily consumed. These terms may be used for meal products and main dish products, provided the product contains 120 cal or less per 100 g.

The terms 'reduced calorie,' 'reduced in calories,' 'calorie reduced,' 'fewer calories,' 'lower calorie,' or 'lower in calories' may be used on the label provided that the food contains at least 25% fewer calories per reference amount customarily consumed than an appropriate reference food.

Sugar content claims include terms such as 'sugar free,' 'free of sugar,' 'no sugar,' 'zero sugar,' 'without sugar,' 'sugarless,' 'trivial source of sugar,' 'negligible source of sugar,' or 'dietarily insignificant source of sugar' and may be used for foods that contain less than 0.5 g of sugars per reference amount customarily consumed and per labeled serving or, in the case of a meal product or main dish product, less than 0.5 g of sugars per labeled serving. Sugar content claims must be immediately accompanied, each time it is used, by either the statement "not a reduced calorie food," "not a low calorie food," or "not for weight control."

The terms 'no added sugar,' 'without added sugar,' or 'no sugar added' may be used only if no amount of sugars or no ingredients that contain sugars, such as jam, jelly, and concentrated fruit juice, have been added. The product must bear a statement that the food is not 'low calorie' or 'calorie reduced' (unless the food meets the requirements for a 'low' or 'reduced calorie' food) and that directs consumers' attention to the nutrition panel for further information on sugar and calorie content.

The terms 'reduced sugar,' 'reduced in sugar,' 'sugar reduced,' 'less sugar,' 'lower sugar,' or 'lower in sugar' may be used on the label, provided that the food contains at least 25% less sugar per reference amount customarily consumed than an appropriate reference food (21 CFR Section 101.60).

'Sodium' and 'Salt' Claims

Sodium content claims include the terms 'sodium free,' 'free of sodium,' 'no sodium,' 'zero sodium,' 'without sodium,' 'trivial source of sodium,' 'negligible source of sodium,' or 'dietary insignificant source of sodium' that may be used on the label, provided that the food contains less than 5 mg (mg) of sodium per reference amount customarily consumed and per labeled serving or, in the case of a meal product or a main dish product, less than 5 mg of sodium per labeled serving. The food must contain no ingredient that is sodium chloride or is generally understood by consumers to contain sodium, unless the listing of the ingredient in the ingredient statement is followed by an asterisk that refers to the statement below the list of ingredients, which states: "Adds a trivial amount of sodium," "adds a negligible amount of sodium," or "adds a dietarily insignificant amount of sodium."

The terms 'very low sodium,' or 'very low in sodium,' may be used on the label, provided that the food has a reference amount customarily consumed greater than 30 g or greater than 2 tablespoons and contains 35 mg or less sodium per reference amount customarily consumed, or the food has a reference amount customarily consumed of 30 g or less or 2 tablespoons or less and contains 35 mg or less sodium per reference amount customarily consumed and per 50 g (for dehydrated foods that must be reconstituted before typical consumption. These terms may be used on the label of meal products and main dish products, provided that the product contains 35 mg or less of sodium per 100 g of product.

The terms 'low sodium,' 'low in sodium,' 'little sodium,' 'contains a small amount of sodium,' or 'low source of sodium' may be used on the label, provided that the food has a reference amount customarily consumed greater than 30 g or greater than 2 tablespoons and contains 140 mg or less sodium per reference amount customarily consumed, or the food has a reference amount customarily consumed of 30 g or less or 2 tablespoons or less and contains 140 mg or less sodium per reference amount customarily consumed and per 50 g (for dehydrated foods that must be reconstituted before typical consumption). These terms may be used on the label or in labeling of meal products and main dish products provided that the product contains 140 mg or less sodium per 100 g.

The terms 'reduced sodium,' 'reduced in sodium,' 'sodium reduced,' 'less sodium,' 'lower sodium,' or 'lower in sodium' may be used on the label or in labeling of foods, provided that the food contains at least 25% less sodium per reference amount customarily consumed than an appropriate reference food.

The term 'salt free' may be used on the label only if the food is 'sodium free.' The terms 'unsalted,' 'without added salt,' and 'no salt added' may be used on the label only if there is no salt added during processing and the food that it resembles and for which it substitutes is normally processed with salt. If the food labeled 'salt free' is not sodium free, the statement, "not a sodium free food" or "not for control of sodium in the diet" must appear adjacent to the nutrition label of the food bearing the claim.

Fat Content Claims

Fat content claims include the terms 'fat free,' 'free of fat,' 'no fat,' 'zero fat,' 'without fat,' 'negligible source of fat,' or 'dietarily insignificant source of fat' or, in the case of milk products, 'skim' may be used on the label provided that the food contains less than 0.5 g (g) of fat per reference amount customarily consumed and per labeled serving or, in the case of a meal product or main dish product, less than 0.5 g of fat per labeled serving.

The terms 'low fat,' 'low in fat,' 'contains a small amount of fat,' 'low source of fat,' or 'little fat' may be used, provided that the food has a reference amount customarily consumed greater

than 30 g or greater than 2 tablespoons and contains 3 g or less of fat per reference amount customarily consumed, or the food has a reference amount customarily consumed of 30 g or less or 2 tablespoons or less and contains 3 g or less of fat per reference amount customarily consumed and per 50 g of food (for dehydrated foods that must be reconstituted before typical consumption). These terms may be used on the label meal products or main dish products provided that the product contains 3 g or less of total fat per 100 g and not more than 30% of calories from fat.

The terms 'reduced fat,' 'reduced in fat,' 'fat reduced,' 'less fat,' 'lower fat,' or 'lower in fat' may be used on the label, provided that the food contains at least 25% less fat per reference amount customarily consumed than an appropriate reference food. The identity of the reference food and the percent (or fraction) that the fat differs between the two foods and are declared in immediate proximity to the most prominent such claim (e.g., 'reduced fat – 50% less fat than the regular brownies')and quantitative information comparing the level of fat in the product per labeled serving with that of the reference food that it replaces (e.g., 'Fat content has been reduced from 8 g to 4 g per serving.') is declared adjacent to the most prominent claim or to the nutrition label.

Reduced fat claims may not be made on the label or in the labeling of a food if the nutrient content of the reference food meets the definition for 'low fat.' Reduced fat may be used on the label of meal products and main dish products, provided that the food contains at least 25% less fat per 100 g of food than an appropriate reference food and the identity of the reference food and the percent (or fraction) that the fat differs between the two foods are declared in immediate proximity to the most prominent such claim (e.g., reduced fat spinach souffle, '33% less fat per 3 oz than the regular spinach souffle').

The term '_ percent fat free' may be used on the label of foods, provided that the food meets the criteria for 'low fat.' A '100% fat free' claim may be made only on foods that meet the criteria for 'fat free,' meaning they contain less than 0.5 g of fat per 100 g and that they contain no added fat.

Fatty Acid Content Claims

The label or labeling of foods that bear claims with respect to the level of saturated fat shall disclose the level of total fat and cholesterol in the food in immediate proximity to such claim each time the claim is made and in type that shall be no less than one-half the size of the type used for the claim with respect to the level of saturated fat.

The terms 'saturated fat free,' 'free of saturated fat,' 'no saturated fat,' 'zero saturated fat,' 'without saturated fat,' 'trivial source of saturated fat,' 'negligible source of saturated fat,' or 'dietarily insignificant source of saturated fat' may be used on the label provided that the food contains less than 0.5 g of saturated fat and less than 0.5 g *trans* fatty acid per reference amount customarily consumed and per labeled serving, or in the case of a meal product or main dish product, less than 0.5 g of saturated fat and less than 0.5 g *trans* fatty acid per labeled serving.

The terms 'low in saturated fat,' 'low saturated fat,' 'contains a small amount of saturated fat,' 'low source of saturated fat,' or 'a little saturated fat' may be used on the label of foods, provided that the food contains 1 g or less of saturated fatty acids per reference amount customarily consumed and not more than 15% of calories from saturated fatty acids. These terms may be used in labeling meal products and main dish products, provided that the product contains 1 g or less of saturated fatty acids per 100 g and less than 10% calories from saturated fat.

The terms 'reduced saturated fat,' 'reduced in saturated fat,' 'saturated fat reduced,' 'less saturated fat,' 'lower saturated fat,' or 'lower in saturated fat' may be used on the label, provided that the food contains at least 25% less saturated fat per reference amount customarily consumed than an appropriate reference food. The identity of the reference food and the percent (or fraction) that the saturated fat differs between the two foods are declared in immediate proximity to the most prominent such claim (e.g., 'reduced saturated fat. Contains 50% less saturated fat than the national average for nondairy creamers'). These claims may not be made on the label of a food if the nutrient content of the reference food meets the definition for 'low saturated fat.'

Cholesterol Content Claims

The terms 'cholesterol free,' 'free of cholesterol,' 'zero cholesterol,' 'without cholesterol,' 'no cholesterol,' 'trivial source of cholesterol,' 'negligible source of cholesterol,' or 'dietarily insignificant source of cholesterol' may be used on the label, provided that the food contains less than 2 mg of cholesterol per reference amount customarily consumed and per labeling serving or, in the case of a meal product or main dish product, less than 2 mg of cholesterol per labeled serving. Additionally, foods must contain 13 g or less of total fat per reference amount customarily consumed, per labeled serving, and per 50 g if the reference amount customarily consumed is 30 g or less or 2 tablespoons or less (for dehydrated foods that must be reconstituted before typical consumption) or, in the case of meal products, 26.0 g or less total fat per labeled serving, or, in the case of main dish products, 19.5 g or less total fat per labeled serving.

For food that contains more than 13 g of total fat per reference amount customarily consumed, per labeling serving, or per 50 g if the reference amount customarily consumed is 30 g or less or 2 tablespoons or less (for dehydrated foods that must be reconstituted before typical consumption) with water or a diluent containing an insignificant amount, as defined in 21 CFR 101.9(f)(1), of all nutrients per reference amount customarily consumed, the per 50 g criterion refers to the 'as prepared' form), or in the case of a meal product, more than 26 g of total fat per labeled serving, or, in the case of a main dish product more than 19.5 g of total fat per labeled serving, they must contain less than 2 mg of cholesterol per reference amount customarily consumed and per labeling serving, or, in the case of a meal product or main dish product, less than 2 mg of cholesterol per labeled serving, and 2 g or less of saturated fatty acids per reference amount customarily consumed or, in the case of a meal product or main dish product, less than 2 g of saturated fatty acids per labeled serving.

The identity of the reference food and the percent (or fraction) that the cholesterol was reduced are declared in

immediate proximity to the most prominent such claim (e.g., 'cholesterol-free margarine, contains 100% less cholesterol than butter').

The terms 'low in cholesterol,' 'low cholesterol,' 'contains a small amount of cholesterol,' 'low source of cholesterol,' or 'little cholesterol' may be used on the label provided that the food contains 20 mg or less of cholesterol per reference amount customarily consumed and 2 g or less of saturated fatty acids per reference amount customarily consumed. Foods must also have a reference amount customarily consumed greater than 30 g or greater than 2 tablespoons and contain 13 g or less of total fat per reference amount customarily consumed and per labeled serving. For foods that have a reference amount customarily consumed of 30 g or less or 2 tablespoons or less and contain 13 g or less of total fat per reference amount customarily consumed, per labeled serving, and per 50 g (for dehydrated foods that must be reconstituted before typical consumption), the food must contain 20 mg or less of cholesterol per reference amount customarily consumed and per 50 g (for dehydrated foods that must be reconstituted before typical consumption) and 2 g or less of saturated fatty acids per reference amount customarily consumed.

Health Claims

The FDA publishes regulations officially recognizing certain associations between food ingredients and health. Depending on the robustness of the scientific data, these may be Qualified Health Claims of Claims of SSA. The greatest threshold for a health claim in FDA's classification is an SSA claim.

In evaluating a petition for an authorized health claim, the FDA considers whether the evidence supporting the relationship that is the subject of the claim meets the SSA standard. This standard derives from 21 U.S.C. 343 (r)(3)(B)(i), which provides that the FDA shall authorize a health claim to be used on conventional foods if the agency "determines based on the totality of the publicly available evidence (including evidence from well-designed studies conducted in a manner that is consistent with generally recognized scientific procedures and principles), that there is SSA among experts qualified by scientific training and experience to evaluate such claims, and that the claim is supported by such evidence." This scientific standard was prescribed by statute for conventional food health claims and by regulation (21 CFR Section 101.14(c)).

Qualified health claims fall short of the threshold for SSA claims. The genesis of qualified health claims was the court of appeals decision in Pearson versus Shalala. In that case, the plaintiffs challenged FDA's decision not to authorize health claims for four specific substance–disease relationships in the labeling of dietary supplements. Although the district court ruled for the FDA, the US Court of Appeals for the DC Circuit reversed the lower court's decision. The appeals court held that the First Amendment does not permit the FDA to reject health claims that the agency determines to be potentially misleading unless the agency also reasonably determines that a disclaimer would not eliminate the potential deception. The appeals court also held that the Administrative Procedure Act required the FDA to clarify the SSA standard for authorizing health claims. In 1999, the FDA published guidance for the submission of health claims, entitled Guidance for Industry: SSA in the Review of Health Claims for Conventional Foods and Dietary Supplements (US Department of Labor, 1999).

Significant Scientific Agreement Claims

The list of currently approved SSA claims includes the following:

- Calcium, Vitamin D, and Osteoporosis (21 CFR 101.72)
- Dietary Lipids (Fat) and Cancer (21 CFR 101.73)
- Dietary Saturated Fat and Cholesterol and Risk of Coronary Heart Disease (21 CFR 101.75)
- Dietary Noncariogenic Carbohydrate Sweeteners and Dental Caries (21 CFR 101.80)
- Fiber-containing Grain Products, Fruits and Vegetables, and Cancer (21 CFR 101.76)
- Folic Acid and Neural Tube Defects (21 CFR 101.79)
- Fruits and Vegetables and Cancer (21 CFR 101.78)
- Fruits, Vegetables, and Grain Products that contain Fiber, particularly Soluble fiber, and Risk of Coronary Heart Disease (21 CFR 101.77)
- Sodium and Hypertension (21 CFR 101.74)
- Soluble Fiber from Certain Foods and Risk of Coronary Heart Disease (21 CFR 101.81)
- Soy Protein and Risk of Coronary Heart Disease (21 CFR 101.82)
- Stanols/Sterols and Risk of Coronary Heart Disease (21 CFR 101.83)

Qualified Health Claims

The list of currently available Qualified Health Claims includes the following:

Qualified Claims about Atopic Dermatitis
- 100% Whey-Protein Partially Hydrolyzed Infant Formula and Reduced Risk of Atopic Dermatitis

Qualified Claims about Cancer Risk
- Tomatoes and/or Tomato Sauce and Prostate, Ovarian, Gastric, and Pancreatic Cancers
- Calcium and Colon/Rectal Cancer and Calcium and Recurrent Colon/Rectal Polyps
- Green Tea and Cancer
- Selenium and Cancer
- Antioxidant Vitamins and Cancer

Qualified Claims about Cardiovascular Disease Risk
- Nuts and Heart Disease
- Walnuts and Heart Disease
- Omega-3 Fatty Acids and Coronary Heart Disease
- B Vitamins and Vascular Disease
- Monounsaturated Fatty Acids From Olive Oil and Coronary Heart Disease
- Unsaturated Fatty Acids from Canola Oil and Coronary Heart Disease
- Corn Oil and Heart Disease

Qualified Claims about Cognitive Function
- Phosphatidylserine and Cognitive Dysfunction and Dementia

Qualified Claims about Diabetes
- Chromium Picolinate and Diabetes

Qualified Claims about Hypertension
- Calcium and Hypertension, Pregnancy-Induced Hypertension, and Preeclampsia

Qualified Claims about Neural Tube Birth Defects
- 0.8 mg Folic Acid and Neural Tube Birth Defects

Qualified health claims are allowed only as described in regulation, which include disclaimers about the quantity or quality of the scientific evidence supporting the health association.

Structure/Function Health Claims

Structure/function claims are the most frequently used of the health claims recognized by the FDA. These claims describe the role of a nutrient or dietary ingredient intended to affect normal structure or function in humans, for example, 'calcium builds strong bones.' In addition, they may characterize the means by which a nutrient or dietary ingredient acts to maintain such structure or function, for example, 'fiber maintains bowel regularity,' 'antioxidants maintain cell integrity,' or they may describe general well-being from consumption of a nutrient or dietary ingredient. Structure/function claims may also describe a benefit related to a nutrient deficiency disease (e.g., Vitamin C and scurvy), as long as the statement also tells how widespread such a disease is in the United States.

The manufacturer may create the claim – there is no prescribed list of claims – but is responsible for the accuracy and truthfulness of these claims. Structure/function claims are not preapproved by the FDA and are held to the standard that they are truthful and are not misleading. Structure/function claims must support a health state and not attempt to ascribe conditions that prevent, cure, or treat a disease. Such statements are understood to be claims made possible only for drugs, and a food so labeled would be subject to seizure as an unapproved drug.

Front-of-Pack Labeling Initiatives

There is an ongoing effort to improve the relevance and utility of nutrition label information to consumers. A variety of nutrition rating systems and symbols appeared on the front of food packages starting in the mid-2000s – meant to make it easier for consumers to make healthful choices. It is possible that the plethora of nutrition rating systems seen in grocery stores today lead to confusion in the grocery aisle and not clarity.

In an effort to address the situation, the US Congress directed the Centers for Disease Control and Prevention to undertake a study with the Institutes of Medicine with additional support provided by the FDA and the USDA. The task was split into two phases. A first report analyzed the nutrition rating systems and the scientific research that underlies them and was released in 2010 (IOM, 2010). The second report delved into consumer use and understanding of front of package systems and was released in 2011 (IOM, 2011).

The report concludes that it is time for a move away from front-of-package systems that mostly provide nutrition information on foods or beverages but do not give clear guidance about their healthfulness and toward one that encourages healthier choices through simplicity, visual clarity, and the ability to convey meaning without written information. The report recommends that the FDA develop, test, and implement a single, standard front-of-pack symbol system to appear on all food and beverage products, in place of other systems already in use. The symbol system should show calories in household servings on all products. Foods and beverages should be evaluated using a point system for saturated and *trans* fats and sodium and added sugars. The more points a food or beverage has, the healthier it is. This system would encourage food and beverage producers to develop healthier fare and consumers to quickly and easily find healthier products when they shop.

The food industry, both manufacturers and retailers, have been active in creating a variety of nutrition rating and symbol schemes, including Facts Up Front, NuVal, and Guiding Stars. The FDA is working to revise and update nutrition labeling in a uniform manner that presents relevant information most clearly to consumers – information that hopefully improves food choices and public health in the long term.

Global Approaches to Food Labeling

The following tables summarize approaches to food labeling in Europe, Asia Pacific, and Latin American regions of the World. For each country identified, the regulatory authority and legal standards, general labeling requirements, nutritional labeling requirements, and general approach to health claims are identified.

Australia

Authority: Food Standards Australia New Zealand (FSANZ)
General Labeling Standard: Part 1.2 of the Australia New Zealand Food Standards Code (ANZFSC)
Mandatory Nutrition Labeling: Yes
Nutrition Labeling Standard: Standard 1.2.8

General labeling requirements	*Nutritional labeling requirements*	*Health claims approach*
Prescribed name or description of the food	Panel must be set out in specific format	All health claims are required to be supported by scientific evidence
Lot identification	Energy	Can be preapproved by FSANZ or self-substantiated by food businesses
Name and business address in Australia or New Zealand of the supplier	Protein	

Mandatory warning and advisory statements	Fat
Ingredient listing	Saturated fat
Date marking	Carbohydrate
Nutrition information panel	Sugars
Percentage labeling	Sodium
Directions for use or storage	Number of servings per package
Country of origin	Serving size

Brazil

Authority: Ministry of Agriculture, Livestock, and Food Supply, National Agency of Sanitary Surveillance (ANVISA)

General Labeling Standard: Resolução RDC n° 123, de 13 de maio de 2004, Lei n° 10.674, de 16 de maio de 2003, Resolução RDC n° 259, de 20 de Setembro de 2002

Mandatory Nutrition Labeling: Yes

Nutrition Labeling Standard: Resolução – RDC n° 360, de 23 de Dezembro de 2003, Resolução RDC n° 359, de 23 de Dezembro de 2003, Resolução – RDC n° 163, de 17 de Agosto de 2006

General labeling requirements	*Nutritional labeling requirements*	*Health claims approach*
Name of food	Serving size with household measurement	All health claims must be approved by ANVISA on a case-by-case basis
Brand	Energy (kcal and kJ)	Foods using health claims on packaging or advertisement must be registered under category of
Quantity indication	Protein	Food with functional properties and health claims'
Net weight	Carbohydrate	
List of ingredients	Total Fat	
Country of origin of manufacturing company	Saturated fat	
Country of origin of importer	*Trans* fat	
Expiration date	Dietary Fiber	
Lot number	Sodium	
Handling information	Vitamins/Minerals	
'Contains Gluten' or 'Does not Contain Gluten' statement	% Daily requirements with reference to the basis in a 2000 kcal, or 8400 kJ diet	
Nutritional information		
Labeling of certain biotechnology ingredients where the genetically modified content of the labeled ingredient exceeds 1%		

China

Authority: Ministry of Health

General Labeling Standard: General Rules for the Labeling of Prepackaged Foods GB 7718

Mandatory Nutrition Labeling: No

Nutrition Labeling Standard: GB 28050. Mandatory for special diet food and principal and supplementary foods for infant and babies and foods making a nutrition claim on package

Nutrition Labeling of Prepackaged Foods

General labeling requirements	*Nutritional labeling requirements*	*Health claims approach*
Product name and description name of food	Energy value (kJ)	Scientific evidence-based approach for approval of health claims
List of ingredients	Protein	Functional foods must be registered with government
Quantitative labeling	Fat	Reduction of disease risk claims and special functional claims must follow GB16740
Net weight and configuration	Carbohydrate	27 Categories of claims are allowed
Address and contact information of manufacturers and distributors	Sodium	
Date of manufacture	Per 100 g or 100 ml and per serving	
Shelf life		
Conditions for the storage		
Food production license number		
Code of the product standard		

Costa Rica

Authority: Ministry of Health, Ministry of Economy and Commerce

General Labeling Standard: RTCA 67.04.54:10 (Central American Technical Regulation)

Mandatory Nutrition Labeling: No. Mandatory when nutritional claims are made RTCA 67.01.60:10

Nutrition Labeling Standard: Not existent

General labeling requirements	*Nutritional labeling requirements*	*Health claims approach*
Product name	Energy value (kJ)	Health claims approved by the FDA, EU, or other recognized governmental agencies can be used. All other claims must be approved by the Ministry of Health

Net content	Protein	A list of preapproved claims is found under Annex G of the regulation
Artificial color and flavors (if any)	Carbohydrates	
Ministry of Health registration number	Fat	
Ingredients listing	Saturated fat only if product contains more than 0.5 g total fat	
Quantity labeling of ingredients	Sodium	
Manufacturer's name and address	Value of nutrients used in claims	
Importer's name and address if applicable	Per serving, 100 g or 100 ml	
Lot number and expiration date		
Country of origin		
Storage and use instructions		

Chile

Authority: Ministry of Health

General Labeling Standard: Decree 977, Title 2

Mandatory Nutrition Labeling: Yes

Nutrition Labeling Standard: Decree 977, Title 2. Nutritional composition and advertisement for foods

General labeling requirements	*Nutritional labeling requirements*	*Health claims approach*
Name of the food product	Energy value in calories	All health claims shall be truthful, proven through scientific methods, and recognized by international organizations
Net content in metric units	Protein Available carbohydrates	There is a list of preapproved health claims
Name or company name and address of the manufacturer, packer, distributor, or importer	Fats	
Country of Origin	Sodium	
Number and date of resolution authorizing import	Quantity of any other nutrient, dietary fiber, and cholesterol, concerning which a representation of properties is made	
Date of manufacture or packing date	Per 100 g or 100 ml, and per serving	
Lot code	Number of servings in the container	
Expiration date or shelf life	Size of each serving	
List of all ingredients		
Instructions for storage		
Instructions for use		

European Union

Authority: European Commission, The Council of the EU, The European Parliament

General Labeling Standard: Current: EC Labeling Directive (2000/13/EC). After December 2014: Regulation 1169/2011 on the provision of food information to consumers

Mandatory Nutrition Labeling: Currently no. Mandatory required if a claim is made. Yes after December 2014

Nutrition Labeling Standard: Council Directive 90/496/EEC

General labeling requirements	*Nutritional labeling requirements*	*Health claims approach*
Name of the food	Energy value	European Parliament and Council Regulation 1924/2006 sets conditions for use for health claims
List of ingredients	Protein	Foods must fit a specific nutrient profile to make health claims Regulation 432/2012 establishes the EU-positive list of 222 approved health claims
References to allergens	Carbohydrate	
QUID information	Fat	
Net quantity	Sugars, saturates, fiber, and sodium shall be declared if a nutrient content claim is made of these nutrients	
Durability indication		
Storage conditions/ conditions of use		
Name and address of food business operator		
Country of origin		
Instructions for use (where required)		
Nutrition declaration		

Abbreviation: QUID, quantitative ingredients declaration.

India

Authority: Ministry of Health and Family Welfare

General Labeling Standard: Food Safety and Standards (Packaging and Labeling) Regulation

Mandatory Nutrition Labeling: Yes

Nutrition Labeling Standard: Food Safety and Standards (Packaging and Labeling) Regulation

General labeling requirements	*Nutritional labeling requirements*	*Health claims approach*
Name of food	Energy kcal	Health claims are classified as: Nutrient function claims, other function claims, disease risk reduction claims
List of ingredients	Protein	Claims related to disease risk reduction shall be made from the list of approved claims (Annexure IV)
Nutritional information	Carbohydrates	Any new claim on disease risk reduction must be authorized
Declaration regarding veg or nonveg: brown color symbol for nonvegetarian; green color symbol for vegetarian food	Sugars	
Statement regarding presence of added colors and flavors	Fat	
Name and address of manufacturer	Other nutrients for which nutrient claims have been made	
Name and address of importer in India if applicable	Amount of vitamins and minerals	
Net quantity		
Lot/code/batch identification		
Date of manufacture		
Best before and Use by date		
Country of origin for imported foods		
Instructions for use		

Japan

Authority: The Ministry of Health, Labor and Welfare (MHLW), The Consumer Affairs Agency

General Labeling Standard: Japan Agriculture Standard Law, Food Sanitation Law

Mandatory Nutrition Labeling: No, except for nutrition claims

Nutrition Labeling Standard: Except for foods with nutrition claims

General labeling requirements	*Nutritional labeling requirements*	*Health claims approach*
Name of the product	Energy	There is a list of health claims preapproved by the MHLW
Country of origin	Protein	All other food for specified health uses claims must be submitted for approval under: regular, qualified, standardized, reduction of disease
Name of the importer	Fat	
Ingredients, other than additives, in descending order of weight percentage	Carbohydrates	
Food additives in descending order of weight on a separate line from other ingredients	Dietary fiber	
The net weight in metric units only	Sodium	
Best-before date	Per 100 g, 100 ml, package or serving	
Storage instructions		
Labeling of certain biotechnology ingredients where the genetically modified content of the labeled ingredient exceeds 5%

Food Law

Food law is a part of the law that encompasses all rules, regulations, case law, and soft law regarding food. This makes food law a 'functional area of law,' placing attention on societal application rather than on doctrinal distinctions. It includes national and international, private and public, criminal and administrative provisions with regard to food.

Most countries of the former British Empire belong to the common law family of law. In food, they have been influenced by the approach in the Adulteration of Food and Drink Act of 1860 and the Food and Drug Act of 1872. This shows that in the central position the concept of 'adulteration' still holds today. From this part of the world, we will discuss food law in the United States.

The civil law family of law – continental European countries and their former colonies – and its related approach to food is represented by the EU. The development of US federal food law dates back to the beginning of the twentieth century. It is mainly based on criminal law approaches. EU food law is halve a century younger. The EU does not have its own system of criminal law. For both reasons, EU food law is mainly based on administrative law approaches. Given this distinction, it may be expected that US food law is drafted in terms of 'don'ts' and EU food law in terms of 'dos.'

Food trade is globalizing. Since the 1960s international standards are developing. International food law has taken up momentum after the entry into force of the WTO agreement in 1995.

Since 1990s the private sector has taken the initiative in regulating (international) trade in food (Figure 1).

This section addresses the international dimension of food law (Section 2), American food law (Section 3), European food law (Section 4), and private food law (Section 5). The last section introduces some organizations active in food law.

International Food Law

In the global arena different players address food. The United Nations (UN) lay emphasis on human rights. The Food and Agriculture Organization (FAO) and the World Health Organization (WHO) have the lead in the core elements of standard setting: risk assessment and risk management. The World Trade Organization (WTO) plays a major role in application of food standards in trade and dispute resolution. WHO operates risk communication structures, seminal in incident management. International food law is a meta-framework (van der Meulen 2011). It does not apply to actions by stakeholders, but makes requirements on national food law that in its turn does address actions by individual stakeholders.

Human Right

The human right to adequate food is recognized in the Universal Declaration on Human Rights (Article 25) and international treaties such as the International Covenant on Economic, Social and Cultural Rights (Article 11). Organizations such as FAO and the UN Committee on Economic, Social and Cultural Rights have further elaborated this right. See, for example, the voluntary guidelines to support the progressive realization of the right to adequate food in the

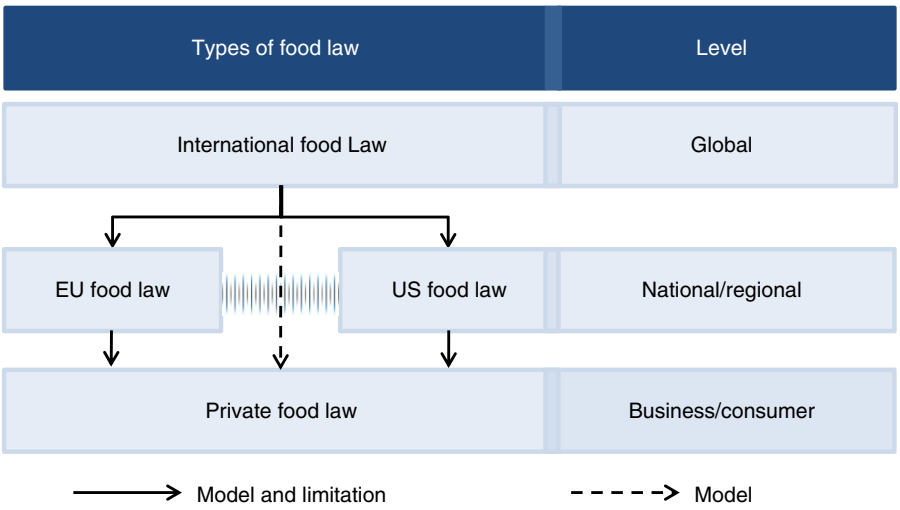

Figure 1 Levels of food law discussed in this contribution.

 doi:10.1016/B978-0-444-52512-3.00053-X

context of national food security at http://www.fao.org/docrep/meeting/009/y9825e/y9825e00.htm. The right to adequate food is realized if people have access to food that

1. provides sufficient nutritional value and micronutrients to lead a healthy and active life;
2. is free of hazardous substances;
3. is acceptable within a given culture.

Complementary to human rights are the state obligations:

1. To respect – generally people can care for themselves and their families. This ability may not be curbed without justification.
2. To protect – if self-sufficiency of citizens is threatened by others the government must do its best to protect them.
3. To fulfill – this obligation encompasses a policy obligation and a relief obligation. A prudent government adopts policies supporting and promoting the ability of the population to provide for itself; it must do its best to provide assistance if people cannot provide for themselves through no fault of their own.

Below we see that mainly the second aspect of adequate food (safety) and the second state obligation (to protect) are taken up in food regulatory systems (Figure 2).

Standard Setting

Risk assessment

Risk assessment for international standard setting is undertaken in three joint FAO and WHO committees: the joint FAO/WHO Committee on Food Additives (JECFA); the Joint FAO/WHO Meetings on Pesticide Residues (JMPR); and the Joint FAO/WHO Meetings on Microbiological Risk Assessment (JEMRA). They advise on maximum limits for food additives, pesticide residues, microbes, and on other food safety issues.

Codex Alimentarius

In 1963, FAO and WHO established the Codex Alimentarius Commission (CAC). CAC established specialized committees, hosted by member states all over the world. 186 CAC members, 185 countries, and the EU are part of the Commission.

Food standards are established through an elaborate procedure of international negotiations (FAO/WHO 2006). All standards together are called 'Codex Alimentarius' (Latin for 'food code'). It also includes advisory provisions called codes of practice or guidelines, mainly addressing food businesses.

At present, Codex comprises more than 200 standards, close to 50 food hygiene and technological codes of practice, approximately 65 guidelines, more than 1000 food additives and contaminants evaluations, and more than 3200 maximum residue limits for pesticides and veterinary drugs (FAO/WHO 2002, FAO/WHO 2006, Masson-Matthee 2007).

Codex procedural manual

The 'constitution' of the Codex Alimentarius is the Procedural Manual. It gives the procedures and formats for setting Codex Standards and Guidelines, and also some general principles and definitions (Table 1). The principles relate among other things to scientific analysis (Table 2).

Codex standards

CAC's work has resulted in a collection of internationally agreed food standards that are presented in a uniform format.

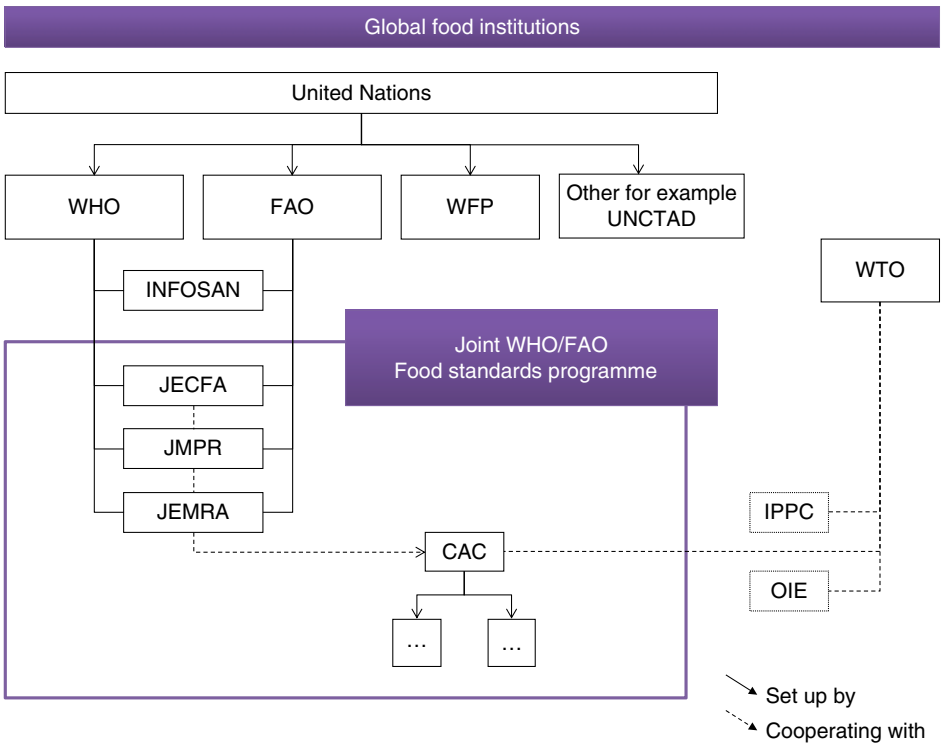

Figure 2 Global food institutions.

Table 1 Some definitions in the Codex Alimentarius Procedural Manual

'Food' means any substance, whether processed, semiprocessed, or raw, which is intended for human consumption, and includes drink, chewing gum, and any substance which has been used in the manufacture, preparation, or treatment of 'food' but does not include cosmetics or tobacco or substances used only as drugs.
'Food hygiene' comprises conditions and measures necessary for the production, processing, storage, and distribution of food designed to ensure a safe, sound, wholesome product fit for human consumption.

Table 2 Example of principles in the Codex Alimentarius Procedural Manual

The food standards, guidelines, and other recommendations of Codex Alimentarius shall be based on the principle of sound scientific analysis and evidence, involving a thorough review of all relevant information, in order that the standards assure the quality and safety of the food supply.

Table 3 Definition of food additive in the Codex General Standard for Food Additives

'Food additive' means any substance not normally consumed as a food by itself and not normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such food results, or may be reasonably expected to result (directly or indirectly), in it or its byproducts becoming a component of or otherwise affecting the characteristics of such foods. The term does not include contaminants or substances added to food for maintaining or improving nutritional qualities.

Table 4 The principles of HACCP according to Codex Alimentarius

Principle 1	Conduct a hazard analysis.
Principle 2	Determine the Critical Control Points (CCPs).
Principle 3	Establish critical limit(s).
Principle 4	Establish a system to monitor control of the CCP.
Principle 5	Establish the corrective action to be taken when monitoring indicates that a particular CCP is not under control.
Principle 6	Establish procedures for verification to confirm that the HACCP system is working effectively.
Principle 7	Establish documentation concerning all procedures and records appropriate to these principles and their application.

Most of these are of a product-specific nature (what in the US are called standards of identity and in the EU vertical legislation). Standards of a horizontal nature are often called 'general standards,' such as the General Standard for the Labeling of Prepackaged Foods (CODEX STAN 1-1985 (Rev. 1-1991)).

According to this general standard, the following information shall appear on the labeling of prepackaged foods: the name of the food; this name shall indicate the true nature of the food; list of ingredients (in particular, if one of a list of eight allergens is present); net contents; name and address of the business; country of origin where omission could mislead the consumer; lot identification; date marking and storage instructions; and instructions for use.

The Codex General Standard for Food Additives (CODEX STAN 192-1995) sets forth the conditions under which permitted food additives may be used in all foods (Table 3).

Codex codes

In addition to the formally accepted standards the Codex includes recommended provisions called codes of practice or guidelines. There is, for example, a set of hygiene codes including the 'Hazard Analysis and Critical Control Point (HACCP) System and Guidelines for its Application' (Table 4).

Legal force

Codex standards do not legally bind. They present models for national legislation. Member states undertake to transform Codex standards into national legislation. However, no sanctions apply if they do not honor this undertaking.

Trade and Dispute Settlement

The WTO was established on 1 January 1995 by the agreement establishing the World Trade Organization as the result of the so-called Uruguay round of trade negotiations and signed in Marrakesh on 15 April 1994 (WTO Agreement). It is the institutional continuation of the General Agreement on Tariffs and Trade 1947 (GATT). It endeavors to liberalize international trade. The basic treaty addressing trade in goods is GATT. GATT recognizes that exceptions to free trade can be necessary to protect higher values such as health and (food) safety.

The agreement on the Application of Sanitary and Phytosanitary Measures (SPS) ensures that countries only apply measures to protect human and animal health (sanitary measures) and plant health (phytosanitary measures) based on the assessment of risk, or in other words, based on science. If the measures are in conformity with international standards, no scientific substantiation of necessity is required. These measures are by definition considered necessary. For food, these international standards are the Codex Alimentarius. This inclusion of Codex in the SPS Agreement greatly enhances its significance. WTO members who follow Codex need not

substantiate the necessity of their sanitary and phytosanitary measures.

WTO agreements bind WTO members. The Dispute Settlement Understanding provides procedures to resolve conflicts. If a party so requires, the Dispute Settlement Body (DSB) forms a panel to adjudicate. Panel decisions can be appealed to the Appellate Body (AB). WTO cannot enforce decisions taken in this procedure; but it can allow the winning party to implement economic sanctions in case of non-compliance. These sanctions are usually additional import levies on goods from the state found at fault.

Incident Management

In case of global food safety incidents such as the Melamine crisis, WHO holds a key position. The International Health Regulations 2005 grant powers to its member states. WHO has set up a worldwide information exchange network INFOSAN (International Food Safety Authorities Network) to enable rapid action.

US Food Law

Constitutional Basis

In the United States of America, food largely is a matter within the powers of the states. The involvement of federal authorities (to which this contribution is limited) is mainly based on Congress' power to regulate interstate commerce (**Table 5**).

Development

Early development of US food law was sparked by economic adulteration, that is, replacing quality ingredients by inferior substances such as addition of chalk to bread and sand to coffee. In 1820, Frederick Accum documented adulteration in the UK. As it was widespread it was difficult to find a single type of food that was not adulterated; he scarcely found some genuine foods (Accum 1820, Hutt and Hutt 1984, Wilson 2008, Fortin 2009).

From the very first, food was regulated in connection with medicinal drugs, and later, medical devices and cosmetics were also regulated. Developments in these areas mutually influenced each other.

Before the independence of the United States, British common law applied the earliest food safety law. The essence was plain and direct: (1) Do not poison food and (2) do not cheat (Hutt 1960, Fortin 2009). 'Adulterated food' in the common law consisted of food that was unfit for human consumption or contained some deleterious substances, whereby rendering it dangerous to health. Packaged food with labels was rare, so there was no common-law offense of mislabeling. However, there existed the offense of falsely representing merchandise for sale (Hutt 1960, Fortin 2009).

Table 5 Article I, section 8, clause 3 of the USA Constitution

Powers of Congress
The Congress shall have Power (...)
To regulate Commerce with foreign Nations, and among the several States, and with the Indian Tribes.

Through the late 1800s, nearly all food laws were state and local. Federal activity was largely limited to regulate imports and exports.

Public support for passage of a federal food and drug law grew as journalists exposed frauds and dangers, such as the use of poisonous preservatives and dyes in food (Fortin 2009). A final catalyst was the 1905 publication of Upton Sinclair's *The Jungle*. Sinclair's portrayal of nauseating practices and unsanitary conditions in the meatpacking industry captured the public's attention. In 1906, President Theodore Roosevelt enacted the Pure Food and Drug Act (21 USC §1 *et seq.*) and the Meat Inspection Act 21 (USC §601 *et seq.*) into law.

Major amendments to these Acts were stalled until the Elixir Sulfanilamide disaster of 1937. The agonizing deaths of more than 100 children spurred the passage of the Federal Food, Drug, and Cosmetic Act of 1938.

In the 1950s, concerns over synthetic food additives, pesticides, and cancer were high. In 1958, the Food Additives Amendment was enacted, requiring the evaluation of food additives to establish safety. The Delaney Clause forbade the use of any substance in food that was found to cause cancer in laboratory animals (Fortin 2009).

In the second half of the first decade of the twenty-first century, a series of high-profile food safety incidents struck the USA. In response, president Barack Obama enacted the FDA Food Safety Modernization Act (FSMA) into law in January 2011. The FSMA places emphasis on preventive food safety systems (Fortin 2011).

Authorities

Regulatory authorities

When the United States Department of Agriculture (USDA) was created in 1862, the Congress authorized it to employ chemists. Eventually, this chemical division became the U.S. Food and Drug Administration (FDA) in 1930 (Hutt 1990, Fortin 2009). FDA was transferred from USDA in 1940 and into the Health Department (now the Department of Health and Human Services) in 1953. FDA received its statutory basis in 1988. Currently, the authority to regulate food is divided among USDA (meat and poultry), FDA (most other foods), and a series of other agencies (with relatively small tasks).

The functions of risk assessment and risk management are combined.

Inspection

The authority to inspect compliance with food law is divided among FDA, state and local governments, two agencies under USDA (FSIS (Food Safety Inspection Service) for meat in interstate commerce and APHIS (Animal and Plant Health Inspection Service) for imports and exports), and several other agencies.

Legislation

Structure of Federal Food Drug and Cosmetic Act

The basic Act in American food law is the Federal Food Drug and Cosmetic Act (FFDCA) (**Table 6**).

Table 6 Definition of food

FFDCA SEC. 201 [21 U.S.C. 321] (f)
The term 'food' means (1) articles used for food or drink for man or other animals, (2) chewing gum, and (3) articles used for components of any such article.

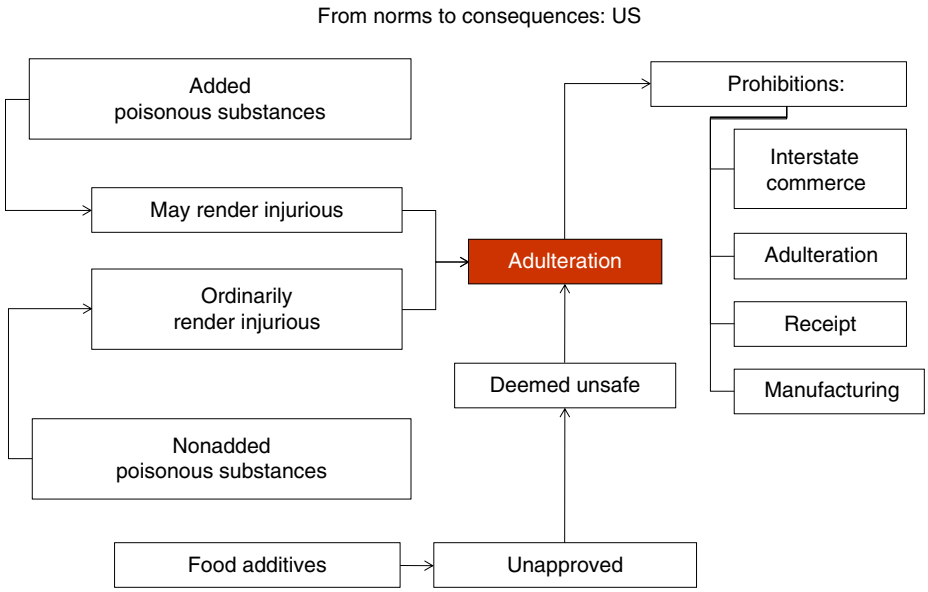

Figure 3 Structure of US food law illustrated as an example of adulteration.

Table 7 Section 402(a)(1) FFDCA

A food shall be deemed to be adulterated if it bears or contains any poisonous or deleterious substance which may render it injurious to health; but in case the substance is not an added substance such food shall not be considered adulterated under this clause if the quantity of such substance in such food does not ordinarily render it injurious to health.

This Act applies a funnel structure. At the heart of the funnel are the concepts 'adulteration' and 'misbranding' (FFDCA Sec. 301 [21 USC §331] Prohibited acts) (All US acts are codified in the US Code. *See* the References section.) All situations regarding food that the FFDCA and regulations based on it try to avoid are defined as fulfilling one of these concepts (Adulteration: FFDCA Sec. 402 [21 USC 342]; Misbranding: FFDCA Sec. 403 [21 USC 343]). To situations of 'adulteration' or 'misbranding', the FFDCA applies prohibitions, penalties, and instruments of law enforcement (FFDCA Sec. 303 [21 USC §333] Penalties).

Consequences

According to Sec. 301 of the FFDCA, the following are prohibited: adulteration or misbranding of food, introduction of adulterated or misbranded food into interstate commerce, receipt in interstate commerce of adulterated or misbranded food, and manufacture of adulterated or misbranded food.

In case of a violation, the perpetrator risks prison of up to 1 year the first time and up to 3 years after a first conviction, or a fine of up to $1000 for first offenders and $10 000 for recidivists.

Further, the FFDCA provides powers of establishment inspection, seizure of products; mass seizure; detention of products, import detention and injunction.

To these powers the FSMA added the power to impose a mandatory recall (Figure 3).

Adulteration

Poisonous or deleterious substance

The concept of adulteration is mainly about the safety of the food, but quality aspects ('economic adulteration') are also taken into account. A difference is made between substances that are added to the food or that are naturally present. To the former a more strict regime applies (Table 7).

Prior authorization

In the 1950s, the USA introduced a requirement of prior authorization for food additives (Table 8). Products within the definition need to be authorized or enjoy Generally Recognized As Safe (GRAS) status. Failing this, foods containing them are considered adulterated (Table 9).

Table 8 Section 201(s) FFDCA [21 USC 321]

The term 'food additive' means any substance the intended use of which results or may reasonably be expected to result, directly or indirectly, in its becoming a component or otherwise affecting the characteristics of any food (including any substance intended for use in producing, manufacturing, packing, processing, preparing, treating, packaging, transporting, or holding food; and including any source of radiation intended for any such use), if such substance is not generally recognized, among experts qualified by scientific training and experience to evaluate its safety, as having been adequately shown through scientific procedures (or, in the case of a substance used in food prior to January 1, 1958, through either scientific procedures or experience based on common use in food) to be safe under the conditions of its intended use (...)

Table 9

FFDCA section 402(2)(C): A food shall be deemed to be adulterated if it is or if it bears or contains any food additive that is unsafe within the meaning of section 409.

FFDCA section 409 (1)(a): A food additive shall, with respect to any particular use or intended use of such additives, be deemed to be unsafe for the purposes of the application of clause (2)(C) of section 402(a), unless (1) ...; (2) there is in effect, and it and its use or intended use are in conformity with, a regulation issued under this section prescribing the conditions under which such additive may be safely used.

Table 10 FDCA SEC. 402. [21 USC 342] (a) (4)

A food shall be deemed to be adulterated if it has been prepared, packed, or held under insanitary conditions whereby it may have become contaminated with filth, or whereby it may have been rendered injurious to health.

This concept of food additive is wider than the concept of food additive in the Codex Alimentarius (and in EU food law) in that it is not limited to substances with a technological function. A food additive that has not been on the US market before 1958 has to undergo safety assessment, except when it is GRAS. In other words, if within the scientific community consensus has been reached on the safety of a certain product (category), it no longer needs to be risk assessed by authorities. On a voluntary basis, FDA's opinion can be sought as to the GRAS status of a product.

Hygiene

Hygiene requirements are also brought within the ambit of the concept of adulteration (Table 10).

The FSMA introduced that food facilities have to implement a written hazard analysis and risk-based preventive control plan (HAPCP). HAPCP is a modernized version of HACCP as elaborated in the Codex Alimentarius and applied in the EU. The main difference is in the focus on hazards generally not limited to critical control points (section 418 FDCA) (Fortin, 2011).

Misbranding

General

The most important requirements regarding labeling have been added to the FFDCA by the Fair Packaging and Labeling Act (1966) and the Nutrition Labeling and Education Act (NLEA) (1990).

From section 403 FFDCA [21 USC 343] follows that a food is misbranded if its labeling is false or misleading in any particular or if the label fails to provide mandatory information.

The most important mandatory requirements are set in regulations by FDA (21 CFR 100–169). The label must indicate: the name of food; the net quantity; the address of producer; and a statement of ingredients and nutrition information. Additionally, imported foods must state their country of origin.

Claims

The topic of claims is addressed in section 403 (r) FFDCA (included by NLEA). Two types can be distinguished: nutrient-level claims and health claims. For nutrient-level claims, 12 terms have been defined in the law. To be labeled 'light,' for example, the product must contain one-third fewer calories or half the fat of the reference food.

A health claim is defined as any claim made on the label or labeling that expressly or by implication characterizes the relationship of any substance to a disease or health-related condition. It is allowed to make a health claim if one of the three conditions is fulfilled: (1) it is authorized by FDA, (2) it is based on an authoritative statement from a scientific body, or (3) if the quality and strength of scientific evidence is not sufficient for authorization by FDA, a qualification to this effect – for example, referring to minority positions in science – can be made.

US (food) law: All US legislation can be approached via the Federal register at http://www.gpoaccess.gov/fr/; all Acts of parliament are codified in the United States Code (USC): http://www.gpoaccess.gov/uscode/index.html; and all regulations are codified in the Code of Federal Regulations: http://www.gpoaccess.gov/cfr/index.html

European Food Law

Treaty Basis

European legislation regarding food is based on the treaty provision on harmonization for the internal market (Article 114 Treaty on the Functioning of the European Union – TFEU) along with the provision on agriculture (Article 38 TFEU) and the instructions to ensure a high level of health protection

(Article 168 TFEU) and a high level of consumer protection (Article 169 TFEU).

Development

Through a reform following the BSE crisis of the 1990s, the food sector has become one of the most regulated sectors in the EU. The dichotomy of adulteration and misbranding does not work very well for analyzing EU food law. Instead, provisions can be categorized as follows (Van der Meulen 2013). There are public powers of law enforcement (Regulation 882/2004) and incident management along with the legislation addressing food businesses.

Most of the legislation addressing food businesses can be further subdivided into one of the three categories: legislation on the product, legislation on the process, and legislation on presentation. The whole structure is embedded in general principles (Figure 4).

Authorities

Risk assessment

In the EU the risk assessment function is separated from the other functions of public authorities. It is the responsibility of the European Food Safety Authority (EFSA) in Parma, Italy.

Risk management

Risk management at the EU level in the form of legislation is the shared responsibility of the European Parliament, the Council, and the European Commission or can be delegated to the European Commission. The Commission can take emergency measures.

Inspection

Official controls are the responsibility of the member states. The European Commission's Food and Veterinary Office (FVO) in Ireland audits the performance of the national competent authorities.

Legislation

Concepts of EU food law

Regulation 178/2002, the General Food Law (GFL), provides some general concepts, obligations, requirements, and principles of food law (Table 11).

Principles of EU food law

Food law should aim at the protection of human life and health and (other) consumers' interests (Article 5 GFL). In protecting life and health it should be science based, that is, to say, based on risk analysis (Article 6 GFL). When scientific

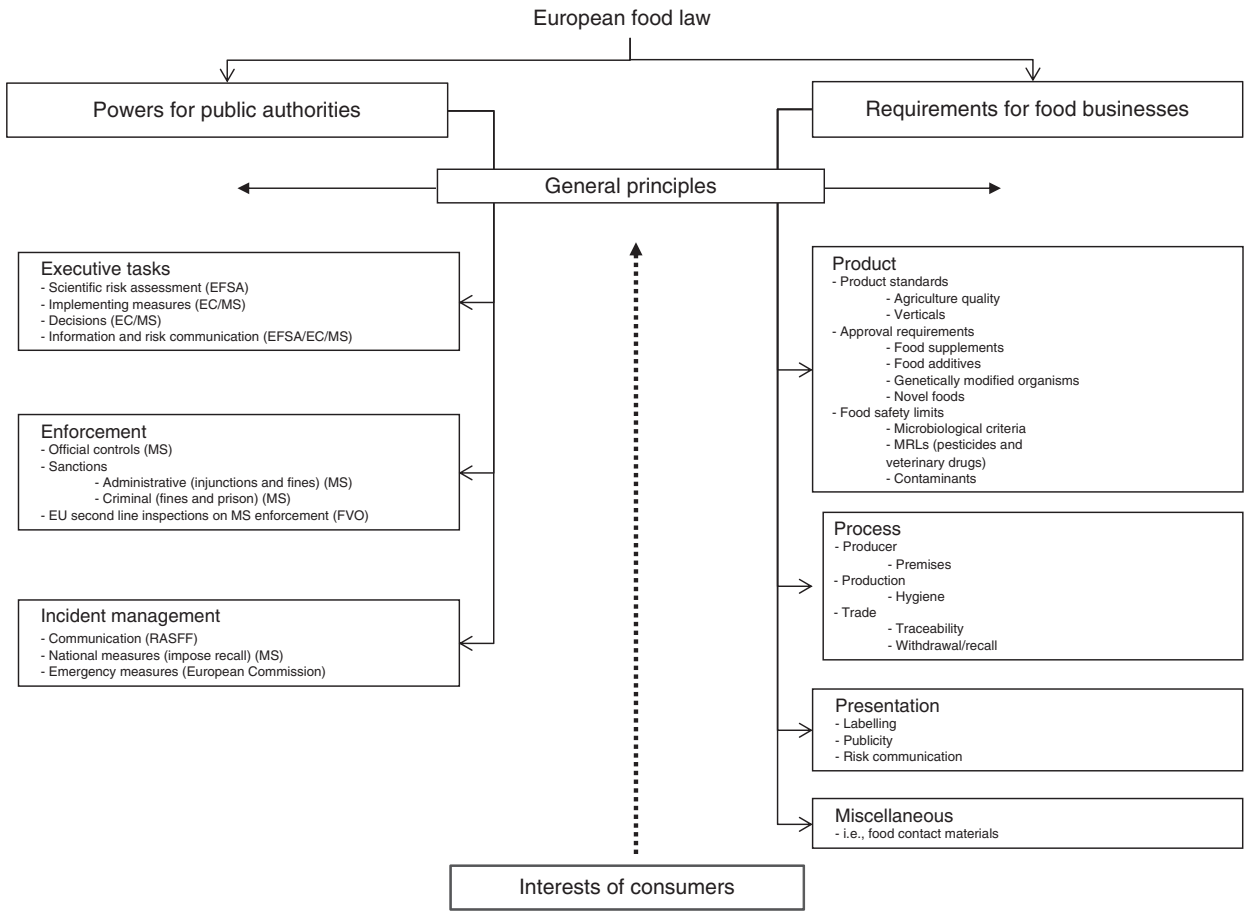

Figure 4 Structure of EU food law.

Table 11 Article 2 Regulation 178/2002 Definition of 'food'

For the purposes of this Regulation, 'food' (or 'foodstuff') means any substance or product, whether processed, partially processed or unprocessed, intended to be, or reasonably expected to be ingested by humans.

'Food' includes drink, chewing gum and any substance, including water, intentionally incorporated into the food during its manufacture, preparation or treatment. It includes water (...).

'Food' shall not include:

(a) feed;
(b) live animals unless they are prepared for placing on the market for human consumption;
(c) plants prior to harvesting;
(d) medicinal products (...);
(e) cosmetics (...);
(f) tobacco and tobacco products (...);
(g) narcotic or psychotropic substances within the meaning of the United Nations Single Convention on Narcotic Drugs, 1961, and the United Nations Convention on Psychotropic Substances, 1971;
(h) residues and contaminants.

risk assessment is inconclusive, the precautionary principle justifies temporary measures to be taken to protect from possible risks (Article 7 GFL).

Where international standards – such as the Codex Alimentarius – exist or their completion is imminent, they shall, in general, be taken into consideration in the development or adaptation of food law (Article 5(3) GFL). The definition of food, for example, is tailored on the Codex and also the principles of HACCP as elaborated in the Codex are incorporated in EU food law.

Food businesses are responsible to ensure compliance. Member states are responsible for enforcement (Article 17 GFL).

Product

Legislation addressing the product falls under three categories: (1) compositional standards, (2) prior authorization requirements, and (3) limits on contamination.

Composition

Vertical legislation, legislation about the composition (recipe) or quality of products, loses in relevance.

Prior authorization

The general rule is that producers are free in their choice of ingredients. Increasingly, exceptions to this rule are made in the sense that approval is required for certain products. Approved products are included in the so-called positive lists (lists of products that may be used).

The most important categories for which approval is required are food additives (Regulation 1333/2008), genetically modified foods (Regulations 1829/2003 and 1830/2003), and novel foods (Regulation 258/97). Food additives are (synthetic) substances that are not foods by themselves but are added to foods for technological purposes such as conservatives, gelling agents, and colors. Genetically modified foods are foods consisting of, or made from, organisms to which gene technology has been applied. Novel foods are all (other) foods that have not been consumed to a significant degree in the EU before 1997.

The most important criterion for authorization is scientific risk assessment. No GRAS exemption exists.

Contaminants

Finally, there is a legislation setting limits to the presence of undesirable substances (contaminants) or organisms in food. (*See* Framework regulation 315/93; Regulation 1881/2006 on mycotoxins and chemicals; Regulation 2073/2005 on microbiological criteria; Regulation 396/2005 on pesticide residues; Regulation 470/2009 and Regulation 37/2010 on veterinary drugs; Directive 96/22 on hormones; and Regulation (EURATOM) 3954/87, Regulation (EURATOM) 944/89 and Regulation 297/2011 on radioactive contamination.) The limits are set on the basis of scientific risk assessment. To residues of products (like veterinary drugs) that have not been approved or for which no lowest safety level can be established, a zero tolerance may apply.

Process

To ensure food safety, processes must be under control in production as well as in trade. Practices aimed at preventing food safety risks are known as 'hygiene.' At the heart of EU legislation on food hygiene is the HACCP system (Regulation 853/2004). It requires food businesses to analyze their processes to establish where hazards may occur, how to recognize them, and how to deal with them to maintain food safety. Application of the system must be documented.

In trade, a requirement of traceability applies (Article 18 GFL). Food businesses must record where their inputs come from and where their products go. If an incident occurs this information must enable authorities to swiftly identify the origin of the problem and its dispersal to eliminate the cause and take care of the consequences.

Finally, businesses that have reason to believe that a food they have brought to the market may not comply with food safety requirements are under obligation to withdraw it from the food chain and recall it from consumers (Article 19 GFL).

Presentation

General

A large part of food legislation addresses the information food businesses provide to consumers regarding their product through advertising and – mainly – labeling (Regulation 1169/2011). Labeling may not be misleading (Table 12).

All prepackaged food products must be labeled in a language easily understood, i.e., in the national language of the member state.

There are approximately 12 required (mandatory) pieces of information, the most important of them are: name under which the product is sold; list of ingredients; quantity of certain ingredients or categories of ingredients; presence of allergens (list of 14); net quantity; date of minimum durability or, in the case of foodstuffs which, from the microbiological

Table 12 Article 2(2)(j) Regulation 1169/2011

'labeling' means any words, particulars, trade marks, brand name, pictorial matter or symbol relating to a food and placed on any packaging, document, notice, label, ring or collar accompanying or referring to such food.

point of view, are highly perishable, the 'use by' date; name or business name and address of the manufacturer or packager, or of a seller established within the Union; and a nutrition declaration.

Specific labeling requirements demand the presence of additives, novel ingredients, and genetically modified organisms to be mentioned on the label.

Claims

Regulation 1924/2006 addresses nutrition and health claims (OJ L 404, 30.12.2006). Nutrition claims must conform to the annex of this regulation, which states among other things that the expression 'light' may only be used in case of a reduction of at least 30% of certain nutrients or energy. Health claims, for example, claims about the effects of a certain food on health must be approved and science based. Foods bearing health claims are sometimes called 'functional foods.' All EU legislation is available at: http://eur-lex.europa.eu/

Private Food Law

Legal Basis

On the basis, mainly, of contract law and, to a lesser extent, some other private law instruments such as intellectual property, a quasi-regulatory framework emerges from the private sector.

Private Standards

For different reasons such as compliance (due diligence) with their own obligations to provide safe food, exporting public law requirements beyond their own territory, chain orchestration and the like, businesses – retail, in particular – have started to require producers to adhere to certain practices formulated in the so-called private standards (also known as private voluntary standards, or private schemes). To prove compliance with the private standard, producers are required to show certification provided by an independent third party (auditor). The owner of the standard licenses the auditor to use the certification mark (a trade mark) and to authorize businesses that pass the audit to use this mark in their communications.

Well known are the food safety standards of the British Retail Consortium (BRC), the International Featured Standards (IFS), the Safe Quality Food (SQF) standards, and ISO 22.000. Outside the domain of food safety, Fair Trade is a well-known private standard.

Content

The content of private standards is defined by a standard-setting organization. This organization can be set up by the businesses requiring the standard to be applied (BRC), by producers and retailers collectively (GlobalGAP), by auditors (Dutch HACCP), by NGOs (Fair Trade) or other, for example, round tables representing different stakeholders, may be including the public sector.

Food safety standards often have the HACCP system as defined in the Codex Alimentarius as their core elaborating on its implementation.

Harmonization

The proliferation of private standards has prompted the largest retailers in the world to set up the Global Food Safety Initiative (GFSI). They have agreed to accept on their shelves products certified for any standard that have passed the GFSI benchmark. In this way it is sufficient for producers to be certified against one single standard instead of many.

Organic

One of the earliest examples of a private standard is the organic standard. It relates to sustainable agricultural practices, in particular, the use of pesticides and fertilizers. In the USA, the EU, and many other countries the organic standard is no longer private but has been incorporated in legislation.

The World of Food Law

The following organizations are relevant in food law.

European Institute for Food Law

The European Institute for Food Law www.food-law.nl is an independent network of food law experts, providing research, consultancy, and training. In cooperation with Wageningen Academic Publishers it publishes a series of books on food law (http://www.wageningenacademic.com/eifl).

European Food Law Association

The European Food Law Association (EFLA) is an association of practitioners (regulatory affairs, legal profession, and government) and academics in food law. The membership is from a wider area than just the EU (www.efla-aeda.org).

European Food Law Association/UK

The UK has a national branch of EFLA (http://www.rdg.ac.uk/foodlaw/efla.htm).

NVLR

NVLR is the national food law association in the Netherlands (http://www.NVLR.nl).

Food Law Academy

The Food Law Academy (www.foodlawacademy.nl/ or http://www.wageningenur.nl/nl/show/Food-Law-2.htm) is a joint venture of the European Institute for Food Law and Wageningen Academy that provides training in food law, such as the annual summer school in food regulatory affairs.

FoodFirst Information and Action Network

The FoodFirst Information and Action Network (FIAN) (http://www.FIAN.org) is an NGO focussing on the right to food comparable to Amnesty International.

Global Harmonization Initiative

The Global Harmonization Initiative (http://www.globalharmonization.net) is an organization of food scientists aiming to support meaningful standard setting through international scientific consensus. A core issue of concern is zero tolerances.

Journals

The most important international journals on food law are the Food and Drug Law Journal (US) (http://www.fdli.org/pubs/Journal%20Online/) and the European Food and Feed Law Review (http://www.lexxion.eu/effl). See also the Journal of Food Law & Policy (http://law.uark.edu/current/journals/journal-of-food-law-policy.html) and World Food Regulation Review (http://www.researchinformation.co.uk/wfrr.php).

Glossary

Community-supported agriculture (CSA) A direct farm-to-consumer marketing arrangement in which consumers purchase shares of a farm's produce, usually in advance, and receive deliveries of fresh produce throughout the growing season. CSA arrangements are sometimes called 'subscription agriculture.'

Concentration ratio The ratio of sales attributed to the *N* largest firms to total industry sales. Concentration ratios reported by the U.S. Census Bureau and used in this article include 4-firm, 8-firm, and 20-firm ratios.

Downstream firms Firms in the food marketing chain that are closer to the final consumer. For example, a supermarket is downstream from a food-processing company.

Everyday low price strategy An approach to supermarket pricing that involves offering relatively stable prices across the store's assortment of products.

Farm stand A direct farm-to-consumer marketing arrangement. A farm stand may be operated from a year-round permanent structure or from a vehicle, trailer, or temporary structure during harvest periods. Stands may be on the farmer's premises but are often at the side of a major highway or thoroughfare.

Farmers' market A facility or area where multiple farmers/growers gather on a regular recurring basis to sell a variety of fresh fruits, vegetables, and other farm products directly to customers. The number of farmers' markets has increased markedly over the past decade making them one of the most prominent direct farm-to-consumer formats.

Pick-your-own operation A direct farm-to-consumer marketing approach that involves the final consumers coming on to the farmer's premises and harvesting produce directly from the field or orchard. The consumer pays the farmer, usually by weight or volume harvested, on leaving the operation.

Promotional pricing strategy An approach to supermarket pricing that involves higher general prices across the product assortment in conjunction with frequent and heavily featured temporary price reductions for selected items. This strategy is alternatively called a high–low (or Hi–Lo) strategy in the academic and trade literature.

Thrifty Food Plan A low-cost but nutritionally balanced basket of food items compiled by the United States Department of Agriculture's (USDA) Center for Nutrition and Policy Promotion. The cost of the Thrifty Food Plan is the basis for Supplemental Nutrition Assistance Program allotments to low-income households.

Upstream firms Firms in the food marketing chain that are more distant from the final consumer. For example, a flour miller is upstream from a bakery.

Introduction

The food marketing system provides the link between farms and consumers. As raw farm commodities move through the food marketing system, a myriad of value-adding activities take place to transform these commodities into something more accessible, more useful, more palatable, or otherwise more attractive to the final customer. In fact, the vast majority of what consumers pay for food represents value that is added by the food marketing system. Statistics compiled by the United States Department of Agriculture (USDA) indicate that farm-gate value accounts for only 15.5 cents of the typical dollar an American consumer spends on food. The remaining 84.5 cents pay for value created by activities in the food marketing system (Canning, 2011).

The marketing system adds value in four ways (Kohls and Uhl, 2002). First, food manufacturers take agricultural commodities and change their form into something more desirable to the customer. This is what happens when a commodity like wheat is transformed into bread. Second, value is added to assembling products that are geographically distant from population centers and making them easily accessible to consumers. The year-round abundance of fresh foods throughout the industrialized world is a testament to the logistical capacity and global reach of today's food distribution system. Third, a steady supply of foodstuffs is facilitated by numerous storage facilities, warehouses, and distribution centers that allow processors and retailers to respond to consumer demands in a timely fashion throughout the year. The fourth, and final, way the marketing system adds value is through activities that facilitate ownership transfer as products move from the farm to the consumer. Brokers, agents, financiers, insurance providers, and many others participate in this system by providing the necessary support services that facilitate food marketing activities.

The activities performed by participants in the food marketing system are in response to important social and demographic changes. Since World War II, the US population has more than doubled in size and has grown in diversity (**Figure 1**). Other sociodemographic shifts included a steady increase in household incomes, a decrease in household sizes, and increased participation of women in the workforce. These trends have fundamentally changed and shaped the demand for food, with emphasis on convenience, ethnic belongingness, and food quality.

The link between diet and health has also become much more important to the calculus of food producers and

 doi:10.1016/B978-0-444-52512-3.00114-5

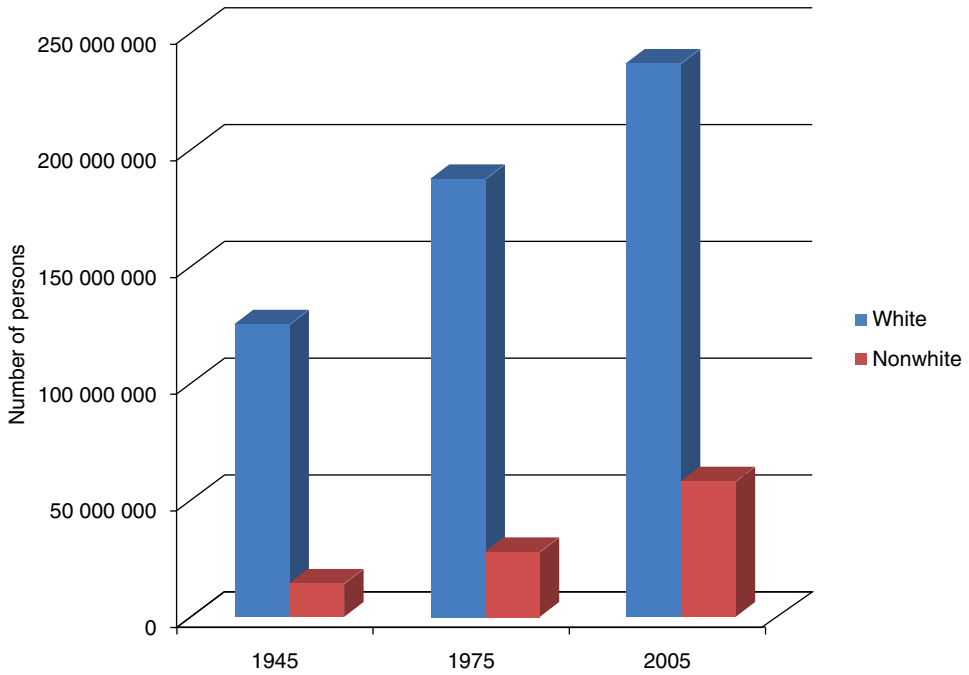

Figure 1 Post-World War II growth in size and diversity of the United States population. Reproduced from Population Estimates, U.S. Census Bureau.

marketers. This is due in part to an aging population. In 1945, only 5.6% of the population was 65 or older compared to 12.4% in 2005 (US Census Bureau, 2013). The population as a whole has also grown more aware of the role of food and lifestyle on health outcomes. Foods are no longer perceived as a means to basic subsistence. Instead, they are also directly linked to health and wellbeing (Siro *et al.*, 2008).

The food marketing system has responded to these trends by building convenience into the food supply, supplying a more diverse array of foods, and innovating into new product offerings (New Products, ERS, USDA, 2013). **Figure 2** shows that over the past 20 years, the number of new product introductions per year has nearly doubled. The decline in the new food and beverage product introductions in the past 2 years is the result of a pullback in discretionary spending from both the producers and consumers during tight economic conditions of the recent recession (New Products, ERS, USDA, 2013).

In the remainder of this article the authors provide a survey of key participants in the food marketing system. The authors first characterize food manufacturers and food wholesalers and then move on to downstream retailers serving the food-at-home (FAH) and food-away-from-home (FAFH) markets. Relatively more emphasis is placed on these downstream participants because upstream segments of the food system are addressed at length elsewhere in this volume. In the latter part of the article, the authors highlight some key issues that are influencing food marketing activities today and that are likely to remain important in the decades ahead.

Food Manufacturers

The food manufacturing industry – NAICS codes 311 and 3121: Food and Beverage Manufacturing (North American Industry Classification System (NAICS), United States Census Bureau, 2002) – transforms raw livestock and agricultural materials into processed food products (including companion/pet food). The food and beverage industry is the largest employer in the entire manufacturing sector and has the largest number of establishments, second only to fabricated metal product manufacturing. Approximately one out of every 10 manufacturing companies is a food or beverage manufacturer, accounting for over 14% of the employment in the whole manufacturing sector in 2011. The bakeries and tortilla manufacturing (NAICS, 3118) accounts for more than a third of the establishments in the food and beverage manufacturing and almost 18% of the employment. Although the meat processing industry accounts for only 12% of the total establishments, it is by far the largest employer in the food and beverage industries.

The contributions of separate food and beverage industries to the total number of establishments and employment are presented in **Table 1**. Although the number of food manufacturers declined from 1998 to 2011 by 8%, the size distribution did not change noticeably (**Figure 3**). Over the reference period, about a third of all food manufacturers are small with less than five employees and more than half of the manufacturing population has less than 10 employees. While all size categories experienced a decline, most of the 8% reduction was absorbed by small manufacturers of less than 10 employees.

Food Wholesalers

Food wholesalers store and distribute food products. They include merchant wholesalers, manufacturers' sales branches, and brokers. The U.S. Census Bureau keeps detailed information on merchant wholesalers in industries like general line

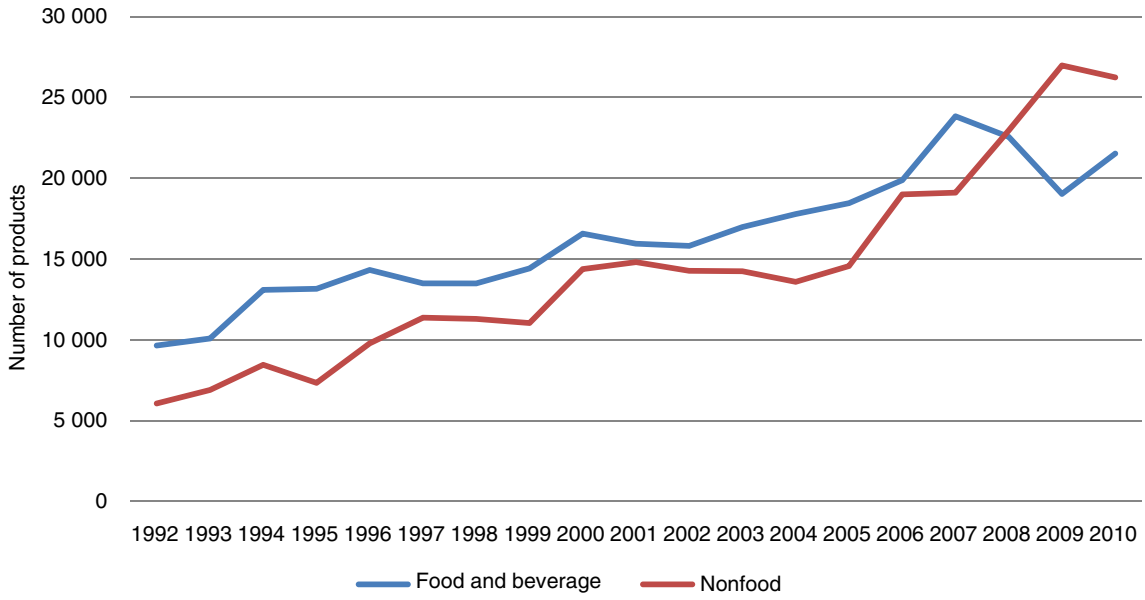

Figure 2 New product introductions of consumer packaged goods, 1992–2010. Data from Datamonitor provided through USDA, Economic Research Service (ERS).

groceries, packaged frozen foods, dairy products, poultry and poultry products, confectionery, meat and meat products, fresh fruits and vegetables, etc.

As a means of cutting costs, retailers have consolidated through mergers. This practice has likely triggered a similar strategy upstream with wholesalers becoming involved in horizontal and vertical mergers to meet larger-scale needs of the retail mergers (Martinez, 2007). Consistent with this trend, data from the County Business Patterns, U.S. Census Bureau, indicate a drop in the number of establishments in all but confectionery merchant wholesalers throughout the period of 2003–11. However, there is no evidence that the number of large wholesalers grew.

The Food-at-Home Market

Firms that sell food items primarily for consumption off premises comprise what is commonly referred to as the FAH market. Statistics compiled by the USDA Economic Research Service indicate that the FAH market in the United States accounted for nearly 676.6 billion dollars in 2011 (United

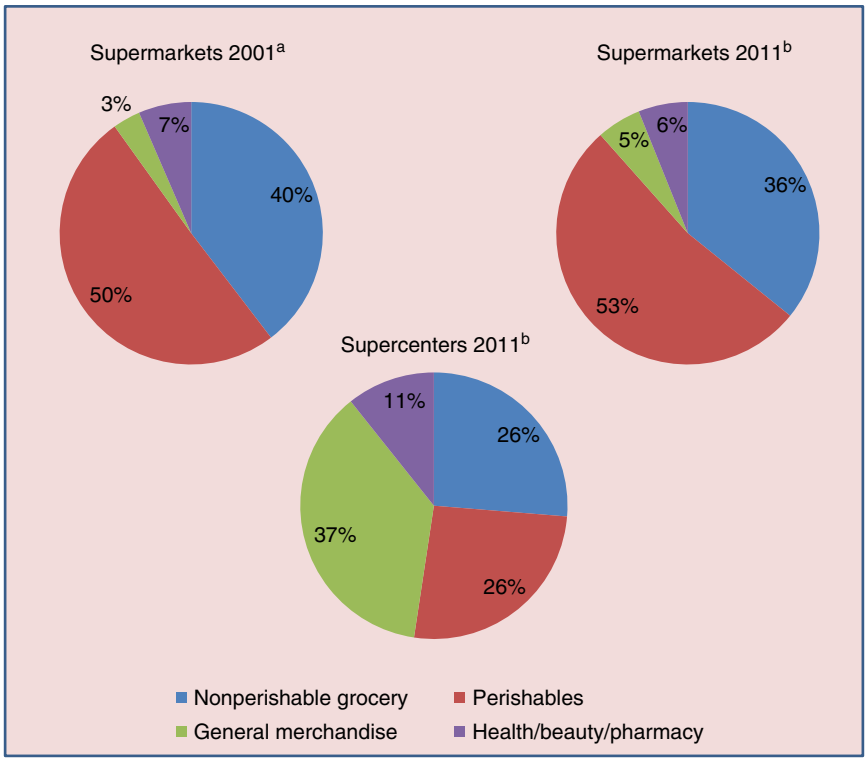
States Department of Agriculture, Economic Research Service (USDA-ERS), 2013). The distinguishing feature of firms in this sector is that they stock a broad array of food items for final sale. Food preparation for on-site consumption may occur at these establishments, and commonly does. However, such food service activities, if they exist at all, are secondary to the sale of grocery and/or perishable foodstuffs.

Retail Formats Serving the Food-at-Home Market

Table 2 lists the retail formats that comprise the FAH market. Supermarkets and supercenters are the dominant retail formats in this sector and accounted for an overwhelming majority of all purchases in 2011. Supermarkets provide a broad array of perishable and nonperishable food items and a full line of nonfood grocery items. Many, if not most, provide service departments such as a delicatessen, an in-store bakery, and/or a pharmacy. The Food Marketing Institute (FMI) defines supermarkets as stores with at least 2 million in annual sales and with a product assortment ranging from 15 000 to 60 000 stock-keeping units (Food Marketing Institute, 2013). Supercenters have grown increasingly important over the past 20 years. The supercenter format combines a discount department store with the perishable and nonperishable food product offerings found in a large supermarket. Examples of this format include Walmart Supercenters and SuperTarget. In comparison to supermarkets, supercenters will commonly have less breadth than supermarkets in some grocery food categories, especially shelf-stable categories such as salad dressings and cake mixes. However, they have a much larger footprint and carry a much broader assortment of nonfood items such as clothing, housewares, electronics, and sporting goods.

Warehouse clubs share the same North American Industry Classification Code as supercenters and so are listed with supercenters in Table 2. Like supercenters, warehouse clubs carry perishable and nonperishable food items along with a

broad array of other merchandise. The breadth of product and brand offerings in food categories, however, is much smaller than would be found in a supermarket or supercenter. Patrons of warehouse clubs include both household and small-business customers who pay an annual membership fee. Items are sold and purchased in much larger wholesale sizes. Sam's Club (Walmart Stores, Inc.) and Costco Wholesale are examples of warehouse clubs.



Retail formats accounting for much-smaller shares of the FAH market include smaller grocery stores and convenience stores, both of which carry a narrower range of grocery items and perishable foods; and specialty food stores such as bakeries, meat markets, and seafood markets. Establishments classified as 'other stores' in Table 2 account for about 5% of the market and include establishments such as drug stores (e.g., Walgreens) and variety stores (e.g., Dollar General) that carry grocery items but derive the majority of sales from items other than food. Mass merchandisers often carry limited selection of food items and accounted for less than 1% of the FAH market in 2011.

Key Features of Supermarkets and Supercenters

As the dominant players in the FAH market, it is worth highlighting the key features of supermarkets and supercenters. Figure 4 presents a rough breakdown in sales for the two retail formats. Perishable food items account for half or more of food and grocery sales in each format. The key difference is the much larger role of general merchandise and health, beauty, and pharmacy products within the supercenter format. This reflects the fact that the leading supercenter chains evolved from discount department stores that were and remain very strong in these items. For supermarkets, Figure 4 shows that the rough breakdown between perishables and groceries has remained remarkably stable over the past 10 years. The slight increase in share of sales from perishables and the 4% reduction in share of sales from groceries can likely be explained by competition between supermarkets and supercenters, with each format playing to its respective strengths.

Figure 5 provides a breakdown of supermarket and supercenter shares by major departments within the store. With exception of floral sales, supermarkets and supercenters account for between 75% and 90% of sales of perishable items. The meat department, fresh produce department, and dairy case are the largest contributors to sales of perishables. Supermarkets and supercenters also account for 74% of grocery food items. They also play important, albeit less dominant, roles in pharmaceuticals, health and beauty products, and nonfood grocery items.

Figure 6 shows that the concentration ratios among supermarkets increased between 1997 and 2002. Consolidation among supermarket businesses via mergers during this

period can explain most of this increase (Martinez, 2007). Between 2002 and 2007, 4-firm and 8-firm concentration ratios have remained remarkably stable and there was only a slight increase in concentration among the 20 largest firms. Although industry concentration measures have been stable, Table 3 reveals that there were important changes to the internal industry structure over the past 10 years. One striking change is the new importance of the supercenter format.

Walmart increased from fourth place in 2002 to first place in 2012 on the list of largest food retailers. Most of the 3217 establishments reported for Walmart in 2012 were supercenters, but this number also includes 170 Walmart Neighborhood Market Stores, which are much closer in size and assortment to a traditional supermarket, and 10 Walmart Express stores. These smaller stores show the company's willingness to explore and branch into additional retail formats, beyond the supercenter. In a recent Progressive Grocer survey, the majority of respondents listed Walmart as a very serious competitive threat. In the South and Midwest, regions where the company has the strongest presence, an even larger percentage (more than 70% of respondents) classified Walmart a very serious competitive threat (Progressive Grocer, 2012a). It is also worth pointing out that Target Stores appears among the top retailers in 2012 providing further evidence of the new importance of the supercenter concept in food retailing. A second noteworthy trend is the growing importance of the 'fresh market' variant of supermarket. This can be seen by the rise in Whole Foods from 27th place in 2002 to 11th place in 2012. Moreover, Trader Joes, not even a top 50 supermarket chain in 2002, was at 12th place in 2012. Both chains emphasize organic food items and sustainable supply chains. They also offer center-of-store brands and assortments that differ markedly from supermarket and supercenter retailers.

Competition and Trade Practices

The full price of a product to consumers includes both (1) the out-of-pocket or monetary cost paid at the cash register and (2) a variety of monetary and nonmonetary costs that are associated with identifying product attributes, prices, and travel to and from the sellers' location. Economists call this latter group of costs as search costs. The primary economic function of food retailers is to reduce search costs by providing consumers access to a broad array of goods and services at one location. According to Richards and Hamilton (2013), supermarkets play an intermediary role and face demands from both food manufacturers and consumers. Manufacturers demand shelf space, which provides access to consumers, whereas consumers demand a broad assortment of products. Competition and trade practices influence the distribution of value among these three groups. Topics of primary interest include choice and management of product assortments, supermarket pricing strategies, and trade arrangements between supermarkets and food manufacturers. Each of these topics is addressed below.

Store assortment

Search costs depend on the number of products carried by the store. The size of supermarkets and the assortment of products contained therein have increased over time. **Figure 7** shows that median square footage increased markedly from 1994 through 1999 and then again from 2003 to 2006. As shown earlier in **Figure 2**, there was also a sizable increase in the number of new products. Sullivan (1997) argues that consumer search costs decline as the number of products increase for the simple reason that it is more likely that the consumer will find the items in his/her desired basket of goods on one shopping occasion and will thereby avoid the need to visit multiple retailers or settle for an actual basket that is incongruent with his/her desired basket. However, Sullivan (1997) also argues that as the assortment of products increases, the addition of more products will have less impact on search costs. This is for two reasons. First, the likelihood that one additional product will match the desired basket declines as the number of products becomes large. Second, a large number of products will increase the difficulty of identifying locating the desired products.

Supermarkets understand the importance of managing product assortment and this is one reason for the emphasis on category management initiatives among food retailers (Van Herpen and Pieters, 2002). Within the supermarket, a category represents a similar group of products and brands. For example, salad dressings, sliced luncheon meats, and prepared breakfast cereals would each be considered a category. Category management involves treating each category as a profit

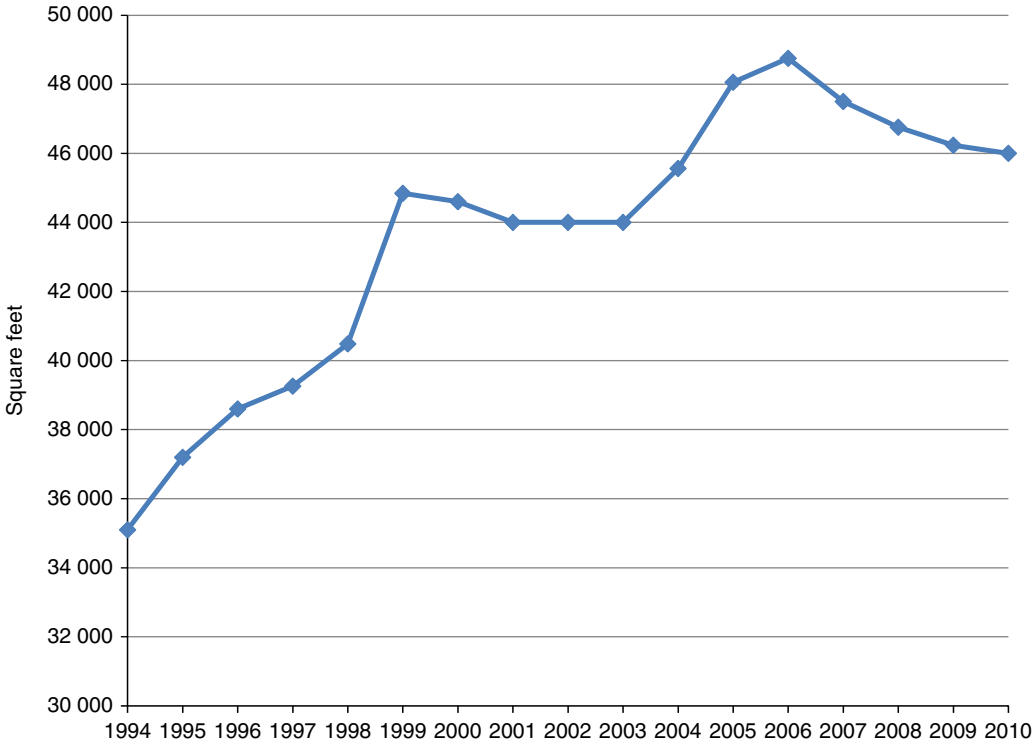

Figure 7 Median supermarket size. One square foot is 0.0929 m^2. Reproduced from Food Marketing Institute (FMI), 2013. Supermarket Facts. Available at: http://www.fmi.org/research-resources/supermarket-facts (accessed 10.12.13).

center. Category managers determine assortments and then price and promote brands within the category in order to maximize category profits (Nijs *et al.*, 2007). Hamilton and Richards (2009) show that optimal assortment depends on the degree of product differentiation within the category. Unsurprisingly, their model suggests that supermarkets will stock fewer product variations within a category when differentiation is low. However, they find that the same is true if differentiation within a category is high. This is because adding new products to the category reduces sales of existing products. The logic from their model is that profit margins are high for highly differentiated products and so the cannibalization effect of deepening the category becomes especially important in these categories. Hamilton and Richards (2009) also show that optimal assortment depends on the degree of differentiation among competing retailers. As consumer loyalty to the retailer increases, they predict that retailers will lower the number of product variants within categories.

Pricing

Approaches to pricing by supermarkets are commonly characterized as (1) everyday low pricing (EDLP) which involves offering relatively stable prices over time across the store's assortment of products or (2) a promotional strategy that involves higher general prices across the product assortment but frequent promotions and temporary (and often steep) price reductions for selected items. Choice between these pricing strategies depends to some extent on clientele being served. Bell and Lattin (1998) find that shoppers making less frequent visits and larger purchases per visit, which they call 'large-basket' consumers, prefer stores that follow an EDLP strategy. However, frequent shoppers with small purchases per shopping occasion tend to prefer stores with a promotional strategy. Bell and Lattin (1998) reason that this is because large-basket consumers will generally need to purchase items from a broad range of categories and are thereby less capable of selectively purchasing from only those categories with a temporary price reduction. Thus, large-basket consumers are primarily interested in the expected price of the overall basket and find EDLP establishments to be the more attractive option. Ellickson and Misra (2008) provide further support for these arguments. They find that the EDLP strategy is preferred by stores in geographic markets with households that are larger, lower-income, and with less access to private transportation.

The degree of industry concentration facing any given geographic market is much higher than the ratios presented earlier in **Figure 3** and so competitive interactions among supermarkets competing for the same geographic customer base are of considerable interest. Ellickson and Misra (2008) examined a national dataset containing store-level information on pricing strategies. Interestingly, their data show that many supermarket chains do not follow a consistent EDLP or promotional strategy chain-wide. In fact, pricing strategies often vary depending on geographic market. Moreover, their results show that competitors in the same geography tend to coordinate on the choice of an EDLP or promotional strategy and that this coordination on pricing strategy cannot be explained solely by similarities in customer and store characteristics. When competitors adopt similar pricing tactics, it is generally thought to facilitate tacit price

cooperation (Besanko *et al.*, 2010), which could then lead to higher consumer prices. Store loyalty programs represent another common strategy that reduces price competition by increasing the costs of switching from one store to another (Kim *et al.*, 2001). Indeed, Hamilton and Richards (2009), mentioned above, show that an increase in-store loyalty causes an increase in price levels along with a decrease in product assortment.

Slotting fees

Slotting fees, payments by food manufacturers to food retailers in return for retail shelf space, have probably been the most controversial topic in relationships between food retailers and manufacturers over the past two decades. These fees were introduced as an industry practice during the mid-1980s (Sullivan, 1997) and are now commonplace in supermarket supply chains. Slotting fees have been the subject of Congressional inquiry and an investigation by the Federal Trade Commission (FTC). Of particular concern is whether slotting allowances hinder competition by providing a mechanism whereby retailers can commit to higher prices and/or whether the practices of paying slotting fees restrict access to retail channels and thereby constitute an entry barrier to would-be food manufacturers (Federal Trade Commission, 2003). Achrol (2012) studied the impact of slotting fees on new product innovation, consumer prices, retailer profitability, and retailer efficiency measures. He concluded that slotting fees have lessened competition among food retailers and have likely contributed to higher consumer prices and higher retail profit margins but less innovation in new product introductions.

More benign explanations for slotting fees have also been put forward, some of which are consistent with economic efficiency. For example, an argument can be made that slotting allowances correct informational problems through the supply chain by allowing manufacturers to make credible signals to retailers about the quality of new product introductions (Federal Trade Commission, 2003). For obvious reasons, retailers would wish to avoid new products that have a low likelihood of success in the marketplace. To the extent that manufacturers are better informed about the prospects of new products, retailers may be reluctant to believe manufacturers' stated claims of product quality when offered new products to add to their assortments. An upfront payment, in the form of a slotting fee, provides the retailer with some assurance that the manufacturer truly believes that the new product is viable. Otherwise, the manufacturer would not possibly be able to recoup the slotting fee through the proceeds of future sales. A slotting fee meets the conditions for what Kirmani and Rao (2000) classify as a default independent signal because the manufacturer bears the cost of the signal regardless of whether the new product turns out to be viable in the marketplace. This means that slotting fees may play another role as well, that of requiring manufacturers to better internalize the risk inherent in new product introductions. When a new product fails, the retailer loses the revenue that could have otherwise have been generated with the space taken by the new product. A slotting fee provides a mechanism whereby the retailer can pass this risk back to the manufacturer (Sullivan, 1997; Federal Trade Commission, 2003).

The FAFH Market

Food services and drinking places (NAICS codes 7221, 7222, 7223, and 7224) engage in preparing and selling meals, snacks, and beverages to customers for immediate on-premise and off-premise consumption. Commonly referred to as food away from home (FAFH), these services include full- and quick-service restaurants, hotels and motels, direct selling at retail stores, bars and vending machines, schools, and colleges, etc.

The food marketing system provided approximately $1.24 trillion worth of food in 2010, almost half of which was provided through food services (Food Service Industry, ERS, USDA, 2012). Due partly to changing sociodemographic profile of the US population, the demand for FAFH has been growing. Households now spend almost half of their food budget on FAFH (**Figure 8**). Several features of the FAFH, convenience, affordability, quality, etc., make FAFH appealing to the population

Figure 9 depicts the FAFH that has become more affluent with smaller household size and more women in the

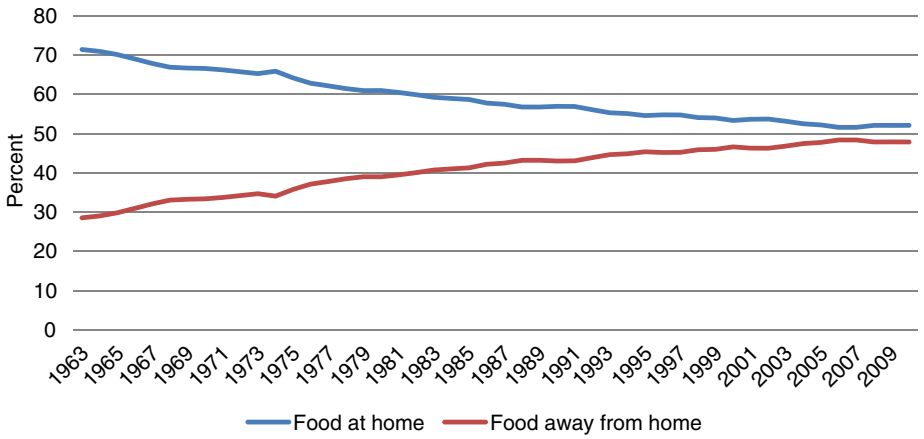

Figure 8 Shares of total food expenditures, 1963–2010. Reproduced from USDA, ERS Food Expenditure Data Series.

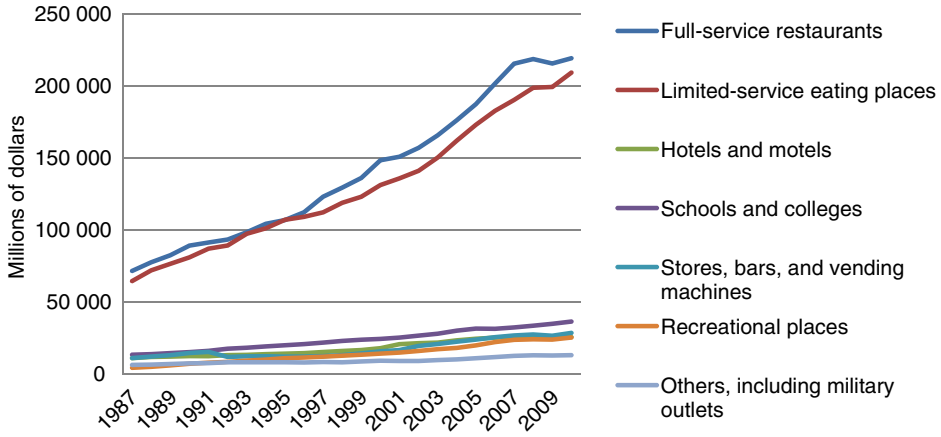

Figure 9 FAFH sales by subcategory, 1987–2010. Reproduced from Food Expenditure Data Series, ERS, USDA.

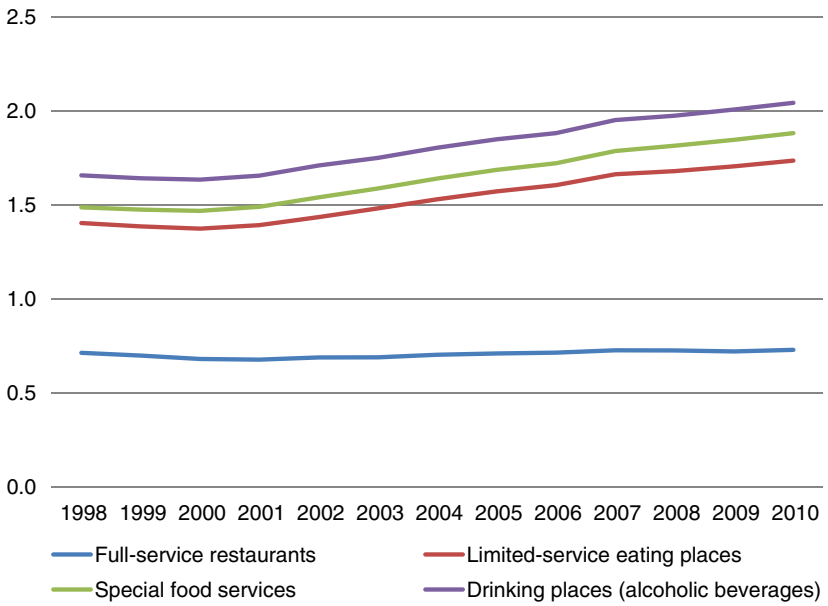

Figure 10 FAFH establishments by subcategory per 1000 population, 1998–2010. Reproduced from County Business Patterns, U.S. Census Bureau.

workforce. The proportion of working women increased from 37.70% of all employees in 1970 to 47.25% in 2010 (U.S. Department of Labor, Bureau of Labor Statistics, 2011).

Expenditure levels by subcategory: The largest two subcategories – full- and quick-service restaurants – account for over three quarters of all FAFH expenditures. These two subcategories mainly differ in services they provide. The quick-service establishments do not generally have waiters/waitresses, and patrons generally order or select items and pay before eating. Full-service restaurants provide waiters/waitresses services and patrons pay after eating.

Over the past decade, the full- and quick-service restaurants held similar market shares. But a closer look at the establishments in the food service category reveals that the market for quick-service restaurant services has grown more rapidly than for full-service restaurants mainly due to convenience of access (Stewart *et al.*, 2004). This trend manifests itself in the growth path of the number of outlets (per 1000 population) in limited- versus full-service subcategories. Although the number of full-service restaurants per 1000 population stayed relatively unchanged in the period of 1998–2010, the corresponding number for quick-service restaurants grew by almost 46% for the same period (**Figure 10**). Nevertheless, the per capita sales in full-service category outpaced that of quick-service category in 1987–2010, except in 1995.

Developments in the demand for FAFH reflect consumers' attitudes toward diet and health as well. Although there seem to be convincing evidence in the literature that meals consumed away from home are more calorie-dense (Lin *et al.*, 1999), the magnitude and direction of the effects of FAFH consumption on weight and health are a matter of ongoing research. Considering the convenience, quality, and practicality of FAFH, it has even been suggested that, despite high calorie density, it should be included in dietary

recommendations such as the Thrifty Food Plan (TFP). You *et al.* (2009) suggest that considering moderate FAFH in the TFP yields similar nutrient and food group composition as the original TFP, whereas greatly increasing the practicality and adaptability of the recommended dietary pattern.

Direct Farm-to-Consumer Markets

There has been growing consumer interest in local foods in recent years. Although 'local' is assumed to relate to geographic proximity, there is no universally accepted definition of local. The Food, Conservation, and Energy Act of 2008 (2008 Farm Bill) defines local foods as locally or regionally produced food products, in which the total distance the product is transported is less than 400 miles from the origin of the product or within the State in which it was produced (Sec. 6015).

Food products with a local origin appeal to consumers for many reasons – environmental, as it helps to avoid long-distance transportation and not contribute to greenhouse emissions; enhancing own-community by providing business to local farmers; security in knowing their food was produced by whom and how; better understanding the origin of their food; perceived better nutritional quality and freshness, etc. Interest in supporting local food systems is also rising among policymakers (Martinez *et al.*, 2010; King *et al.*, 2010).

Local foods are typically marketed directly to consumers (direct-to-consumers) or directly sold to restaurants, retail stores, schools, etc. The latter is referred to as direct-to-grocer/restaurant or intermediated (Low and Vogel, 2011). Direct-to-consumer marketing is done through farmers' markets, community-supported agriculture (CSAs), farm stands, 'pick your own,' etc.

Beginning with the 1997 Census of Agriculture, USDA's National Agricultural Statistics Service (NASS) has collected information on direct-to-consumer marketing outlets that sell food for human consumption. This is the only measureable indicator of direct-to-consumer marketing channel for local foods (Martinez *et al.*, 2010). According to this source, 136 817 farmers sold $1.21 billion worth of farm products directly to consumers in 2007. This is an increase from 93 140 farmers with sales level of $0.55 billion a decade ago (**Figures 11** and **12**). Although the majority of operations engaged in direct-to-consumer marketing are small, for example, less than $25 000 (**Figure 11**), the bulk of sales is easily attributable to large operations (**Figure 12**). Vegetable and fruit farms dominated the direct-to-consumer sales by generating $679 million or 56% of the total sales, whereas only 26% of the operations are produce farms. Although almost a quarter of all direct-to-consumer operations are in beef cattle ranching and farming, their contribution to the total sales is marginal, in the range of 6–12%. Operations in direct-to-consumer marketing in North Central, West, and Northeast regions generated the highest levels of sales and have the highest growth rates from 1997 to 2007 (Diamond and Soto, 2009).

Low and Vogel (2011) estimate that foods marketed exclusively through intermediated channel (direct-to-grocer) generated $2.7 billion in local food sales. This is three times higher than the value of foods marketed exclusively through direct-to-consumer and two times higher than the value of local foods marketed by using a combination of direct-to-consumer and direct-to-grocer channels. They also report that small farms with annual sales less than $50 000 are more likely to rely exclusively on the direct-to-consumer channel. Medium-sized firms (annual sales between $50 000 and $250 000) are likely to rely either on direct-to-consumer marketing or a mix of direct-to-consumer and intermediated channels. Large farms (annual sales $250 000 or more) are equally likely to use either exclusively or both.

Selected Issues in Food Marketing

The U.S. food market has undergone major changes in the past couple of decades. New products as well as new ways of producing, processing, packaging, and handling food products

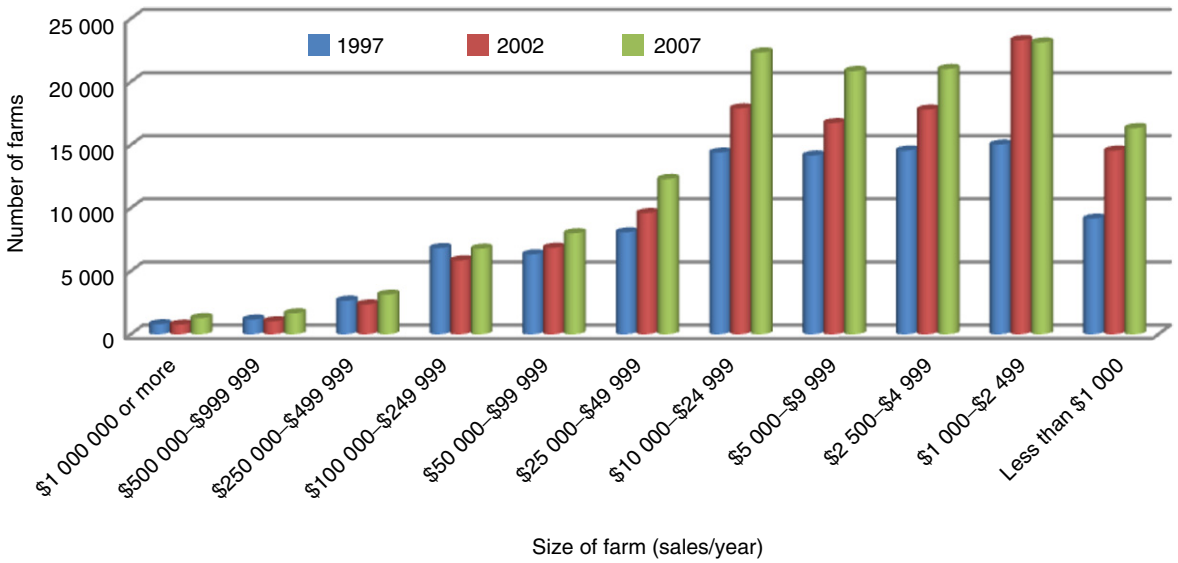

Figure 11 Number of farms marketing directly to consumers by farm size. Reproduced from Census of Agriculture, NASS, USDA.

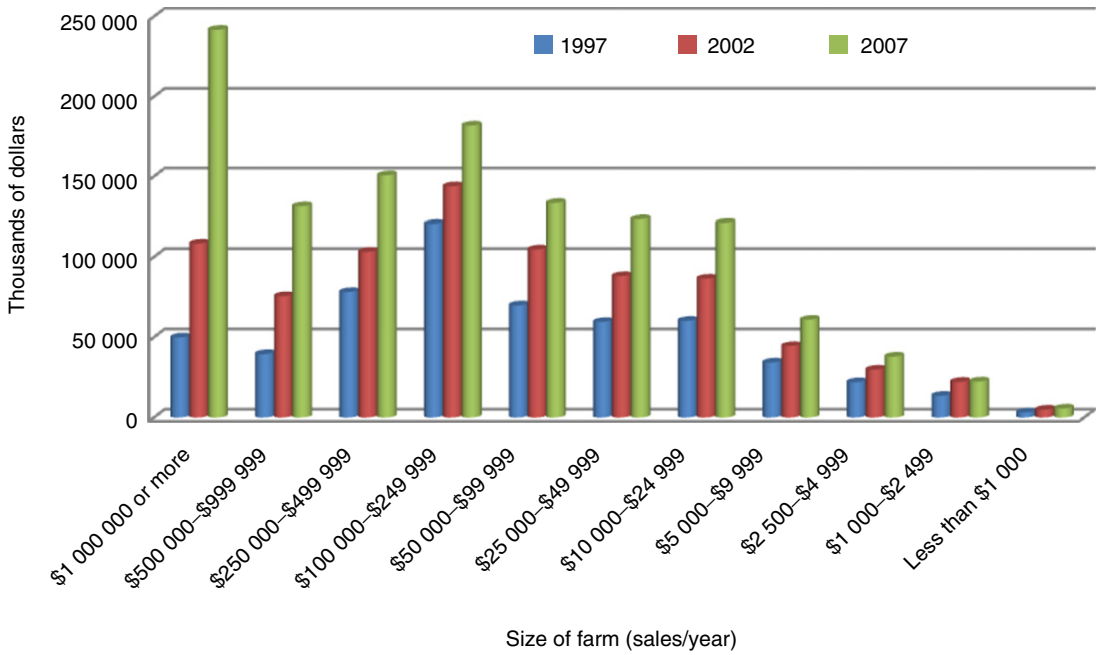

Figure 12 Sales for direct-to-consumer farms by farm size. Reproduced from Census of Agriculture, NASS, USDA.

have emerged. There are several factors that have brought about these changes on food markets. Some of these important factors that will be discussed in Sections are Health Concerns, Nutritional labeling, Food safety, and Functional foods as well as environmental and sustainability issues.

Health Concerns

There is no question that nutrition and health issues are in the forefront of many individual, government, and societal concerns (Nayga, 2008). For example, poor diets and rising obesity rates now dominate the current food, nutrition, and health policy debate in many countries including the United States. Globally, the increasing obesity rates are going to be a major issue and challenge not only for individual choices but also for public policies and programs. Increasing understanding of the correlation between diet and health issues such as obesity, chronic disease, stroke, etc., has also led to significant changes in food markets. According to a report by National Alliance for Nutrition & Activity (NANA), obesity rates have doubled in adults and tripled in children and adolescents over the past two decades. This is a major concern given that obesity increases the risk of cancer, heart disease, diabetes, high blood pressure, and arthritis-related disability (National Alliance for Nutrition & Activity, 2010). All these diet-related health problems have fueled consumers to demand more information about the nutritional content and safety of the food products they buy. As a result, the US government has introduced a number of regulations to help consumers make informed decisions when purchasing and consuming food products.

Nutritional labeling

Food labeling became a concern as the food-processing industries were rapidly increasing. The first regulation on food labeling was passed in 1906, and it mainly addressed the issue of food adulteration or misbranding. It was not until 1973 when nutritional content was first included on the food label. Over the years, food labeling has undergone many changes in an attempt to provide consumers with the necessary information about food products. The most significant development on food labeling came about after many scientific research and important reports from the Surgeon General, the National Academy of Sciences, and the Institute of Medicine increasingly revealed the close relationship between diet and health (Gillet, 2011). Concerns about the obesity issue and the effect of diet on health have partly resulted in the legislation of the Nutrition Labeling and Education Act (NLEA) in 1990. The NLEA regulations require the display of a 'Nutritional Facts' panel on processed foods. The panel also provides information about the standard serving size and a breakdown of nutritional content including calories. Elements such as total and saturated fats, cholesterol, and sodium must always be shown, whereas other nutrients can be suppressed if they are zero. The regulations also update the list of nutrients that appear on the nutritional facts panel and define nutrient content claims and health claims.

Although the NLEA mandates the mandatory nutritional labeling of food products, it only covers the FAH market (i.e., food products sold in grocery stores). It does not cover the food away from home market which includes fast-food restaurants and cafeterias. Food consumption trends in the United States, however, have changed significantly over the past 20 years as previously discussed. A quick look back four to five decades shows an extremely different household structure compared to today, namely, a two-parent, single-income household where the wife was a stay-at-home mother. Given the norms in that era, the wife tended to prepare each meal at-home, eliminating much of the need to

eat-away-from home. In 1960–61, approximately 21% of the food allocated budget was spent away-from-home. This share has increased significantly since the 1960s with close to half of the food budget now being spent away-from-home (Department of Labor, 2006). Numerous factors have contributed to increased consumption of food away from home, most notably: more women in the workforce, more two-income households, and advertising and promotion by food chains.

Many studies have reported a correlation between food away from home consumption and obesity (Kruger *et al.*, 2008; Boutelle *et al.*, 2007; Chung *et al.*, 2007; Duffey *et al.*, 2007; Schröder *et al.*, 2007; Niemeier *et al.*, 2006; Taveras *et al.*, 2005; Bowman *et al.*, 2004; Kant and Graubard, 2004; Mancino *et al.*, 2004; Thompson *et al.*, 2004; Binkley *et al.*, 2000). Eating more fast-food meals has also been linked to eating more calories, fat, saturated fat, and sugary soft drinks and less fruits, vegetables, and milk (e.g., Boutelle *et al.*, 2007; Schröder *et al.*, 2007; Taveras *et al.*, 2005). Consequently, as obesity is becoming a more serious issue, health-consciousness has powered the trend toward full nutrition disclosure in restaurants as well. In fact, in March 2010, the US Congress passed a national law requiring chain restaurants with 20 or more outlets to list calories and other nutrition information on menus and menu boards (Center for Science in the Public Interest, 2013). Although some restaurants have been supportive of this idea and have tried to help FDA write some of the regulations regarding menu labeling in restaurants, many other 'ready-to-eat' food enterprises have opposed these new regulations. Part of the opposition is due to menu-related obstacles, including too many menu variations, limited space on the menu for labeling, and loss of flexibility in changing the menu. There are also personnel-related obstacles that include difficulty in training employees to implement nutrition labeling, and not enough time for food service personnel to implement nutrition labeling. However, despite the obstacles of menu labeling, this regulation seems to have a lot of support from American consumers. An estimated 78% of Americans support menu labeling in restaurants (Department of Public Health, CO, 2010).

Food safety

Despite the fact that food has never been as safe as it is today, food safety remains a major issue. The Centers for Disease Control and Prevention (CDC) estimated that in the United States, roughly 1 in 6 Americans (or 48 million people) gets sick, 128 000 are hospitalized, and 3000 die of foodborne diseases every year (see Centers for Disease Control and Prevention, 2013). Although developments related to the adoption of Hazard Analysis Critical Control Point (HACCP) and other safety standards may have helped reduce the incidence of foodborne illness in the United States, infections with *Salmonella*, *Escherichia coli* O157:H7, *Campylobacter*, and *Listeria* remain and are alarmingly an ever-present phenomenon.

There has been some progress though. For example, data released through FoodNet comparing 2011 with 2006–08, rates of infection were significantly lower for *Shigella* (43% decrease) and *E. coli* O157 (25% decrease), and higher for *Campylobacter* (14% increase) (**Figure 13**). The incidence did not change significantly for *Cryptosporidium*, *Listeria*, *Salmonella*, *Vibrio*, and *Yersinia* infections. In addition, the overall incidence of infection with six key pathogens transmitted commonly through food was significantly lower in 2011 compared with 1996–98 (**Figure 14**). For individual pathogens, the incidence of infection was significantly lower in 2011 compared with 1996–98 for *Shigella* (65% decrease), *Yersinia* (52% decrease), *E. coli* O157 (42% decrease), *Listeria* (35% decrease), and *Campylobacter* (22% decrease), but was higher for *Vibrio* (76% increase). It did not change significantly for *Salmonella* or *Cryptosporidium*.

Who are at greater risk of foodborne illness? They are the children and the elderly. The incidences of laboratory-confirmed infection with *Campylobacter*, *Cryptosporidium*, *Salmonella*, Shiga toxin-producing *E. coli* (STEC) O157 and

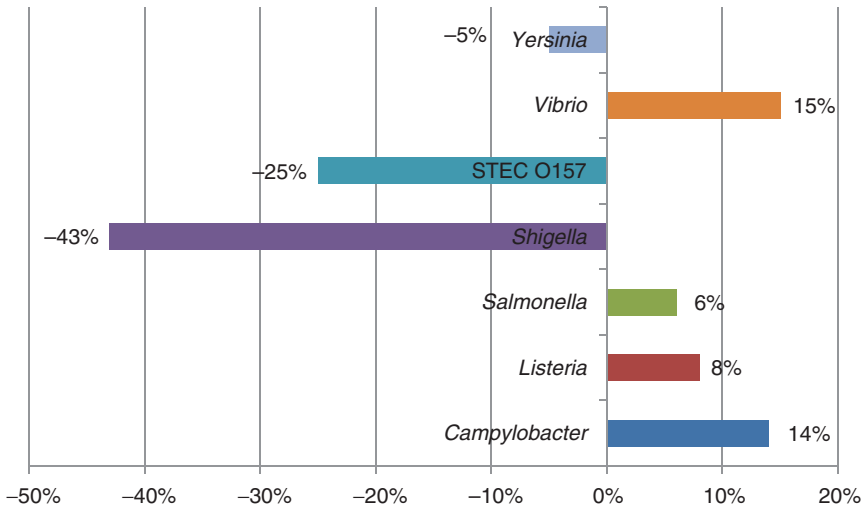

Figure 13 Incidence of laboratory-confirmed bacterial infections: percentage change in 2011 compared with 2006–08. Reproduced from Foodborne Diseases Active Surveillance Network (FoodNet), CDC. Available at: http://www.cdc.gov/foodnet/data/trends/trends-2011.html/ (accessed 10.12.13).

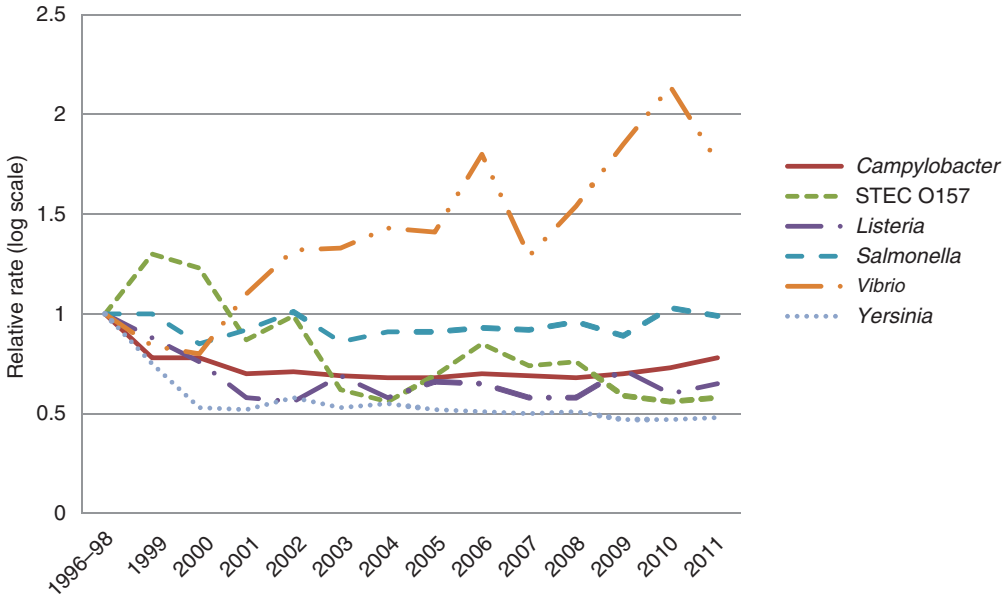

Figure 14 Relative rates of laboratory-confirmed infections with *Campylobacter*, *E. coli O157*, *Listeria*, *Salmonella*, and *Vibrio*, compared with 1996–98 rates, by year – Foodborne Diseases Active Surveillance Network, United States, 1996–2011. Reproduced from Foodborne Diseases Active Surveillance Network (FoodNet), CDC. Available at: http://www.cdc.gov/foodnet/data/trends/data-for-figures-2011.html#data-fig3 (accessed 10.12.13).

non-O157, *Shigella*, and *Yersinia* have been highest among children aged <5 years, whereas the incidences of *Cyclospora*, *Listeria*, and *Vibrio* infection have been highest among adults aged ≥65 years. Young children and older adults were also more likely to have severe complications or die from these illnesses. Thirteen percent of infections, 24% of hospitalizations, and 57% of deaths occurred among adults aged ≥65 years.

Budget declines have led to a governmental decision to cut funds on different programs including food safety programs. This is expected to also affect food markets. As food safety programs are trying to hunt down foodborne illnesses, a slowdown in this progress is expected to occur as a result of the US government budget cuts or 'sequester.' For instance, USDA has already projected that food safety will be particularly hard hit by furloughs, as approximately 87% of the budget will now go to food inspectors and 'support' for inspectors (Parnass, 2013).

One recent development related to food safety was the start of a new livestock identification program to help agriculture officials track livestock in cases of disease. This program helps ensure that sick animals' movements can be reviewed as part of an effort to control the spread of the disease. It also means that healthy animals can continue to move freely to processing facilities and also help investigators determine the source of a disease and whether it happened naturally or if someone tampered with the food system. Although this new program, which took into effect in March 2013, is mandatory, it applies only to animals being shipped across state lines. It also gives states flexibility in deciding how animals will be identified.

Functional foods

Health-related concerns have an influence on decisions made by consumers to reduce the consumption of harmful ingredients (e.g. fats and salt) and to increase the consumption of beneficial food components into their diets (Brown and Schrader, 1990; Capps and Schmitz, 1991; Chang and Kinnucan, 1991). According to Willett (2002), 60% of the risk of chronic diseases potentially is preventable with lifestyle modifications, including changes in diet. Consequently, functional foods have increased in popularity in recent years. Functional foods generally are defined as foods or food components that may provide a health benefit beyond basic nutrition. Functional foods are believed to offer consumers an increased ability to reduce the risk of certain diseases or health problems (Schmidt, 2000). Research conducted by the International Food Information Council (2005) showed that consumer demand for functional foods has increased steadily since 1996, which makes the development of these types of products potentially profitable (Singletary and Morganosky, 2004). It is no surprise then that many food companies now are developing food products with functional or health-related attributes.

In addition to functional foods, there is also an increasing demand for food products that reflect the growing trend of food allergenicity. For example, the NPD Group, a provider of market information and advisory services, is continually tracking top dieting and nutrition-related issues facing consumers and reported that 1 in every 3 adults claimed to cut down or avoid gluten completely in January 2013. Interest in gluten-free menu items at restaurants also is growing. In NPD's CREST® food service market research, which tracks daily how consumers use restaurants, consumers are asked if they ordered something off the menu that was listed as high protein, whole grain, sugar-free, or described in another way. The incidence of consumers ordering food described on the menu as gluten-free or wheat-free has grown over time and is now more than double what it was 4 years ago.

Environmental and Sustainability Issues

In addition to an increasing demand for functional foods, there is an increasing demand for sustainable food products. Examples of this trend are demand for local and organic food, as well as demand for carbon footprint information in food production.

Organic products

Organic foods now occupy prominent shelf space in the produce and dairy aisles of most mainstream US food retailers. The marketing boom has pushed retail sales of organic foods up to $21.1 billion in 2008 from $3.6 billion in 1997. The US organic industry grew as an increasing number of retailers sell a wider variety of organic foods through the development of private-label product lines by many supermarkets, and the widespread introduction of new products.

A broader range of consumers has also been buying more varieties of organic food. Organic handlers, who purchase products from farmers and often supply them to retailers, sell more organic products to conventional retailers and club stores than ever before. Ironically, however, organic farms have struggled at times to produce sufficient supply to keep up with the rapid growth in demand, leading to periodic shortages of organic products.

Food miles and local foods

In recent years, expansion of international food trade has significantly increased the transportation of food products around the world with negative impacts on the environment. Food transportation, especially by air and road, consumes large quantities of fuel and energy, releasing greenhouse gases (GHG) which contribute to global climate change. Food that is sourced by the major retailers from global supply chains can be imported from many thousands of miles (Smith *et al.*, 2005; Kloppenburg *et al.*, 1996). The globalization of food-supply chains exacerbated the problem and led to the situation where information on where the food comes from and information about the social and environmental impacts associated with production and transportation of food are less visible to consumers. The majority of food consumed today passes through a complex network of a few large, centralized producers, processors, transporters, and distributors before reaching the final marketplace.

This trend has prompted many consumers to question the environmental and social sustainability of their food choice. As previously discussed in the Section Health Concerns, food safety and environmental issues as well as ethical motivations related to food production and processing are some of the reasons that concern consumers. Consequently, demand for alternative foods, such as local food, is increasing dramatically. This fact is confirmed by the growing number of alternative food markets and local producer/consumer networks recorded in the United States. According to the Agricultural Marketing Service, there are now over 5274 farmers' markets operating in the country, up from 1755 in 1994.

Recent media and grassroots interest is using food miles, which is the distance food travels from the time it was produced until it reaches the consumers (Paxton, 1994), as a metaphor to explain several benefits associated with local food systems. However, the concepts of local food and food miles have become powerful polemical tools in policy discourses built around sustainable alternative food systems (Coley *et al.*, 2009; Lang and Heasman, 2004). Another debate on the food miles concept concerns the appropriateness of using food miles as a transport emission indicator. Distance traveled is not necessarily a good indicator for transport emissions, and fails to consider other environmental impacts (including other GHG emissions) associated with food production. For instance, Saunders *et al.* (2006) showed that the energy used in producing lamb in the UK is four times higher than the energy used by New Zealand lamb producers, even after including the energy used in transporting New Zealand lamb to the UK. Thus, lower food miles do not necessarily mean lower environmental degradation. Therefore, the issue about the environmental effects of food miles is still under debate in the scientific literature because a number of studies have provided inconsistent empirical evidence on whether domestic or imported food products generate a greater environmental impact (Carlsson-Kanyama, 1997; Blanke and Burdick, 2005).

However, despite some questions remaining on whether imported or local food is more sustainable, food miles information is increasingly being used as a quality cue of food products, in both the global and local markets. In the local market scenario, the implementation of a labeling scheme on food miles might also reflect consumers and local producers' growing interest on environmental characteristics of food products.

Carbon footprint

Food's carbon footprint is the GHG emissions produced by growing, rearing, farming, processing, transporting, storing, cooking, and disposing of the food. Owing to increasing interest in environmental and sustainability issues, there is an increasing demand from consumers and private industries to reduce carbon or GHG emissions associated with food production. Hence, the market for sustainable products is expected to expand significantly in the future.

It is also no longer just environmentalists and policymakers who are concerned about GHG emissions but also food producers and retailers. For example, Walmart has announced plans to label each of its products with a sustainability rating and has subsequently requested that every Walmart supplier provide information about its GHG footprint, a direct measure of climate impact. Walmart has also developed their own 'sustainability index,' which they said will create a more transparent supply chain and drive product innovation.

Summary

The food industry is often characterized as mature and stable in the popular press. The overview provided here shows that consumer food markets are, in fact, quite dynamic and are responsive to consumer demands. Food markets have evolved, along with changing consumer demographics, into sophisticated and efficient systems that supply a broad array of fresh and processed food items sourced from all over the world.

Competition in consumer food markets is especially interesting. Over the past decade, new formats such as warehouse clubs and, especially, supercenters have become a key factor influencing competition in the retail food market. Innovative fresh market retailers that emphasize organic foodstuffs and sustainable supply chains are also emerging as important players. Finally, traditional food retailers face competition from food service firms as time-strapped consumers devote more and more of their food spending to the away-from-home market. As food retailers have consolidated, the sector has caught the interest of academicians interested in market organization and regulatory agencies concerned about fair trade practices.

The article also addressed the consumer and regulatory trends that are shaping the food marketing system in the United States and around the world. These include concerns about food and health. Specific issues in this arena include food safety, the role of the food marketing system in rising rates of obesity and associated health problems, and the development and promotion of functional foods. These concerns are behind recent changes in food safety policy and nutrition labeling. Consumers are also more interested about the source of their foods and the effect of their foods on the environment. This is one factor behind the growth in direct farm-to-consumer market venues and to sustainability initiatives by processors and retailers. These trends provide challenges as well as opportunities for the food system in the coming decades.

Introduction

Importance of Microorganisms in Foods

Every food harbors its own microbiota that may be specific and characteristic of a given point in the production process and of storage conditions. In processed foods, the microbiota consists of microorganisms from the raw materials that survived the processing, preservation, and storage conditions as well as microorganisms that contaminated the food during handling and processing. In raw foods, their characteristics, handling, and environmental conditions as well as farming practices will dictate the predominating microbiota.

Some microorganisms can be considered useful, if the changes due to their growth in foods are deemed beneficial, for example, in terms of flavor, texture, and appearance. But microorganisms can also be able to spoil foods. From the point of view of sensory rejection (deterioration), the spoilage microbiota consists of microorganisms that can grow on a food, causing undesirable changes. The potential of microorganisms to spoil food rests on their ability to produce metabolites that are associated with spoilage and that will lead to rejection of foods by consumers. In general, many microorganisms in a food are capable of producing undesirable metabolites when they grow above a certain level (Gram *et al.*, 2002). The growth of spoilage microorganisms in foods may result in changes in sensory properties, such as color, odor, texture, and appearance. Additionally, some microorganisms pose a health risk, and they are considered pathogenic. The characteristic of the disease will depend on a number of factors inherent to the food, pathogenic microorganism, and affected individual.

There are many microorganisms that are naturally present in foods, sometimes as contaminants. Bacteria stand out the most, both as pathogens and as spoilage microorganisms. For example, *Pseudomonas* spp. and other Gram-negative psychrotrophic microorganisms can be responsible for reduction of shelf life of high-protein, chilled foods stored under aerobic conditions, such as meat and dairy products. *Pseudomonas* is associated with postprocessing contamination of pasteurized milk Eneroth *et al.* (2000). *Shewanella putrefaciens* is an example of psychrotrophic microorganism responsible for the deterioration of chilled seafood (Chai *et al.*, 1968). Although vegetative forms of microorganisms play an important role in food spoilage, spore-forming bacteria are of great relevance for processed food, such as canned foods, vacuum-packaged meat, and thermally processed foods, because their spores survive lethal treatments (Ternstrom *et al.*, 1993).

In addition to bacteria, fungi are a very important group to be concerned with. Fungi are involved not only in food production but also in their spoilage and mycotoxin production, which may have several adverse effects to human and animal health. Fungi may gain access to foods through different routes, such as in the field (pre- and postharvest and during processing and storage). Fungi are the most diverse microorganisms of importance for food industry as they can grow on many different substrates with varied water activity (a_w), pH, and temperature (Dao and Dantigny, 2011). These microorganisms have developed mechanisms that allow them to adapt to high acidic conditions (Prusky and Yakoby, 2003), very low a_w, such as 0.75, and to survive thermal processing (Dao and Dantigny, 2011).

Viruses, protozoan, and parasites play a major role as causes of foodborne diseases in several countries. These microorganisms have variable resistance to lethal treatments used in food processing. Although they all share a common characteristic of not being able to grow in foods, they may be able to survive in these substrates.

Factors Affecting Microbial Behavior in Foods

The fate of microorganisms in foods depends not only on the physical and nutritional characteristics of the food but also on a set of extrinsic and intrinsic factors of the food and their interactions. Factors, such as temperature, pH, water activity, and redox potential, can be considered the most important factors driving microbial fate in foods. Food industry takes advantage of the fact that these factors can be conveniently manipulated to prevent microbial contamination and growth in foods.

Temperature

Among factors affecting microbial behavior in foods, temperature is for sure the most important one. According to Jay (2000), microorganisms can be classified into three groups according to their growth temperature domains: Psychrotrophs grow well at 7 °C or below and have an optimal growth temperature range of 20–30 °C; mesophiles grow well between 20 and 45 °C and have an optimal growth temperature range of 30–40 °C; and thermophiles grow well at 45 °C or higher and have an optimal growth temperature range of 55–65 °C. Most foodborne pathogens are mesophilic microorganisms, with exception of *Listeria monocytogenes*, *Yersinia enterocolitica*, and *Clostridium botulinum* type E, which have markedly psychrophilic behavior. *Alicyclobacillys*, *Geobacillus stearothermophilus*, and *Bacillus sporothermodurans* are examples of thermophilic microorganisms of importance in foods and beverage industries.

Storage at low temperatures is one of the most important ways of slowing microbial metabolic activity in foods. However, cellular sensitivity to cold stress depends on many factors, including temperature, cooling/freezing rate, culture medium, strain, and storage time (Beales, 2004). It has been well

documented that microorganisms adjust the lipid composition of their membranes in response to temperature changes to insure membrane functionality (Russell, 1984; Mastronicolis *et al.*, 1998). Microorganisms growing at low temperatures change the fatty acid composition of their phospholipids and glycolipids to optimize membrane fluidity. This is necessary for nutrients to continue passing through the membrane and for cellular respiration (Berry and Foegeding, 1997).

Reduction of temperature leads to increase of lag time in foodborne microorganisms, culminating with the extension of shelf life. Therefore, it is one of the most used methods to preserve shelf life of minimally processed, pasteurized, and raw foods. Low temperatures will inhibit the development of mesophiles and thermophiles, but not of psychrotrophs. The growth of psychrotrophic microorganisms can be inhibited by adjusting other extrinsic and intrinsic parameters.

pH

It is well established that most microorganisms grow better in pH values close to 7.0, although a few can grow in pH values below 4.0. Bacteria tend to be more sensitive to pH than filamentous fungi and yeasts, and pathogenic bacteria are even more sensitive. Spoilage microorganisms of the lactic acid bacteria (LAB) group, for example, may grow in pH values as low as 2.0. Pathogenic microorganisms, such as *Cl. botulinum*, will not grow in pH values below 4.6. Because of its pathogenic potential, pH 4.6 is used as a limit for a food to be classified as of low acidity (>4.6) or high acidity (<4.6). The pH has a marked importance in the definition of intensity of thermal processing, with low and high acid foods being processed above and below 100 °C, respectively.

The minimum and maximum pH values tolerated by each microbial species depend also on other factors. For example, the minimum pH required for the growth of certain lactobacilli depends on the type of acid used: Citric, hydrochloric, phosphoric, and tartaric acids enable growth at lower pH values than acetic and lactic acids (Jay, 2000). Minimum concentrations of these acids or preservatives are used for inactivating or inhibiting microorganisms. In principle, growth could be inhibited by inactivation or disruption of the cell membrane, cell wall, metabolic enzymes, protein synthesis, or genetic material (Eklund, 1989).

Although the pH 4.6 marks the point below which pathogenic microorganisms cannot grow, the occurrence of several outbreaks associated with acidic products, such as fruits and fruit juices, have shown that inability to grow in foods with $pH<4.6$ should not be confounded with ability to survive.

All microorganisms have an optimal pH range for their growth and survival, and they are more sensitive to internal than external pH changes. When these changes are significant, they may lead to loss of viability. Acids usually inhibit essential reactions by increasing the concentration of hydrogen ions, which reduces the internal pH of the cell. The cell's ability to grow depends on its ability to change the environmental pH enough to reach its optimal range (Jay, 2000). Filamentous fungi have developed a mechanism to circumvent the effect of weak acids and keep homeostasis and internal pH. This mechanism requires adenosine triphosphatase (ATPase), which helps to remove excess protons from the cell (Beales, 2004). Hence, filamentous fungi and yeasts are capable of tolerating lower pH values than bacteria and are associated with the spoilage of acidified foods and products made with acidic fruits. Many microorganisms in more acidic environments than the ideal may require a higher minimum temperature for growth and even a higher minimum water activity (Booth and Stratford, 2003).

Water activity

Water activity is related to the amount of water available for the metabolic reactions within the cell. In fresh foods, a_w exceeds 0.99 (Jay, 2000). In general, bacteria need higher water activity than fungi, and Gram-negative bacteria need higher water activity than Gram-positive bacteria. Most bacteria associated with food spoilage grow at a_w above 0.91, whereas most filamentous fungi can grow at a_w as low as 0.80. *Staphylococcus aureus* can grow at a_w of 0.86, whereas *Cl. botulinum* needs a_w of at least 0.94. Like filamentous fungi, yeasts can withstand lower pH than bacteria, and the same goes for water activity. The lowest water activity required by a bacterium is 0.75 (halophilic bacteria), whereas xerophilic molds and osmophilic yeasts can grow at a_w of 0.65 and 0.61, respectively (Jay, 2000). The general effect of reducing water activity to a value below the optimum value is to increase the lag phase and reduce growth rate. Lowering the water activity causes what is known as osmotic stress.

Most microorganisms have evolved to function only within certain water activity ranges. Water activity outside the optimal range may reduce the essential metabolic functions of the cell and inhibit a large part of the physiological processes, such as nutrient absorption (Roth *et al.*, 1985) and deoxyribonucleic acid replication (Meury, 1988). In response to osmotic stress, microorganisms produce biocompatible solutes, such as trehalose, glycerol, sucrose, and mannitol. These biocompatible solutes help to balance the osmotic pressure of the cell and preserve protein function (Beales, 2004).

Other factors

It is evident that water activity and pH interact with temperature, because individual microorganisms or groups grow in a wide range of storage conditions. In addition to temperature, pH, and water activity, other factors are also important, such as the redox potential (Eh), packaging system, food structure, relative moisture, and atmospheric composition. Some anaerobic bacteria such as those from the genus *Clostridium* need an environment with reduced Eh to grow ($Eh=-200$ mV), whereas those from the genus *Bacillus* require positive Eh to grow. The bacteria that grow better in slightly reduced Eh conditions are called microaerophiles, which includes some LAB, such as *Lactobacillus* (Jay, 2000).

Studies have also discussed how the presence and concentration of some gases in the environment prevents or promotes microbial growth. Oxygen prevents the growth of anaerobic microorganisms in modified packaged foods, but high concentrations can increase the speed of oxidation reactions or even allow the faster growth of aerobic microorganisms. Carbon dioxide is the gas used in modified atmosphere packages that possess antimicrobial properties. Nitrogen is not absorbed by foods and is used as filler gas. The

atmosphere within the packages will be different depending on foods packaged, storage conditions, and package material. Several studies have been performed regarding the fate of foodborne microorganisms in modified packaged foods. However, the major concern in these products is related to the potential growth of psychrotrophic pathogens, such as *L. monocytogenes*. Some examples include the growth of *Listeria innocua* in fresh cut mixed leafy salads packaged in modified atmosphere (Scifò *et al.*, 2009) and survival of *L. monocytogenes* and *Salmonella* Enteritidis in sea bream packaged in modified atmosphere enriched with carbon dioxide (Provincial; Guillen *et al.*, 2013).

The combination or interaction of extrinsic and intrinsic parameters is very important for controlling microbial growth. Considering this, the concept of hurdle technology has been developed and applied for production of several foods, such as salami. The hurdle technology considers the combination of extrinsic and intrinsic factors aimed at increasing the stability and safety of foods, but at the same time insuring freshness and nutrition of foods.

Even with the application of multiple barriers to guarantee shelf-stable and safe products, microorganisms will use mechanisms to adapt to function optimally in physiologically normal environments. Any extreme change in environmental conditions causes stress on the microorganism, which may result in loss of viability or sublethal injuries leading to inactivation or inability to grow in foods.

To survive in foods, microorganisms have developed physiological and genetic mechanisms that enable them to withstand stressful conditions, such as cold shock, preservatives, heat shock, etc. For example, when exposed to cold shock, some microorganisms can produce specific protein groups, called cold shock proteins, which enable them to adapt and survive cold. The addition of preservatives, such as sorbates and benzoates, also activates specific repressor genes, which are probably necessary for optimal adaptation of microorganisms to preservatives, weak acids, and low pH (Beales, 2004). A low–medium pH lowers the inner pH of microbial cells to a point that the cell can no longer tolerate, inhibiting their development. However, some microorganisms can survive this stress by making use of passive and active mechanisms to regulate the inner pH of the cells.

The principles and mechanisms associated with the interaction of extrinsic and intrinsic factors should always be taken into account, whether it is for the formulation of a new product or the establishment of a new process.

Microbiological Spoilage of Foods

Bacterial spoilage of foods

Although many bacteria can grow in foods, only some specific groups are responsible for their spoilage (**Table 1**). The survival, growth, and occurrence of these microorganisms in foods are affected by many different factors, including storage temperature, oxygen availability, food composition, pH, thermal treatment, and competing microbiota, among others.

Bacterial spoilage occurs faster and more evidently in high-protein foods, such as meat, milk, fish, and dairy products. Most of these foods are rich in nutrients and have high water activity as well as pH values close to 7.0 Huis in't Veld, 1996. However, the occurrence of certain microorganisms in these foods is mainly promoted by temperature and atmosphere. Temperature is a limiting factor as it can favor the growth of some spoilage microbial groups and impair the growth of others. For example, low temperature favors the growth of psychrotrophic bacteria over the growth of mesophiles and thermophiles. In this context, *Pseudomonas* spp., a strictly aerobic psychrotrophic bacterium, prevails as the main spoilage microorganism in chilled fresh meat and may cause color, odor, and flavor changes as it degrades amino acids and fats (Gill and Newton, 1978; Labadie, 1999). They create a slimy layer on the surface of the food as they grow. This species, together with *S. putrefaciens*, *Photobacterium phosphoreum*, and some *Vibrio* spp., is the main microorganism involved in the spoilage of seafood (Broekaert *et al.*, 2011; Chai *et al.*, 1968; Gram and Huss, 1996; Gram and Dalgaard, 2002). Moreover, *Pseudomonas* spp., together with other psychrotrophic species, is responsible for proteolysis and hydrolytic rancidity of raw milk and dairy products and also for changes on the surface (slime), pigmentation, and odor of cheeses (Champagne *et al.*, 1994). Despite the high fat content of butter and cream, these can also be spoiled by this group of bacteria (Wang and Frank, 1981). In addition to changes promoted by psychrotrophic and LAB, cheese may also be spoiled by coliforms (early blowing) or gas-producing, anaerobic, spore-forming bacteria, such as *Clostridium tyrobutyricum* (late blowing) (Ledenbach and Marshall, 2010). Eggs are a very popular food and are also used as ingredients in many foods. They have many barriers that prevent the access and growth of microorganisms within them. The prevailing microbiota in the spoilage of this product is composed of Gram-negative bacteria, including *Pseudomonas* spp., which rot the product and change its color (Shebuski and Freier, 2010).

A small change in the way a food is packaged, such as the use of vacuum or modified atmosphere, can change the profile of the spoilage microorganisms from aerobic to facultative or strictly anaerobic. In meats and meat products stored under these conditions, spoilage is caused by LAB, Enterobacteriaceae, and sometimes *Brochothrix thermosphacta* (Dainty and Mackey, 1992). *Brochothrix thermosphacta* is an important species associated with the spoilage of meats and meat products and grows in both aerobic and anaerobic conditions (Pin *et al.*, 2002; Russo *et al.*, 2006).

Other changes in the spoilage microbiota of high-protein foods may be induced by changing water activity and adding a competing microbiota. For example, curing, salting, and fermenting meat products inhibits the growth of the natural spoilage microbiota and promotes the growth of bacteria better adapted to these conditions, such as species of the genera *Micrococcus* and *Staphylococcus* and some LAB (Cerveny *et al.*, 2010; Huis in't Veld, 1996; Samelis *et al.*, 2000).

The presence of complex nutrients in fruits and vegetables, such as cellulose, polysaccharides, hemicellulose, and pectin and in some cases the acidic pH, limits the bacterial spoilage of these foods. However, some bacteria are capable of producing extracellular lytic enzymes that degrade these polymers, releasing nutrients for their growth. This softens the flesh and produces acids, alcohols, and metabolites with unpleasant odors and flavors. The main bacterium species responsible for

Table 1 Main bacteria involved in the spoilage of specific food groups

Types of food	*Main groups responsible for spoilage*	*References*
Refrigerated, fresh meats (aerobic atmosphere)	*Pseudomonas* spp. and other psychrotrophs	Ellis and Goodacre (2001); Gill and Newton (1978)
Refrigerated, fresh meats (vacuum or modified atmosphere)	*Brochothrix thermosphacta*, *Clostridium* spp., *Shewanella putrefaciens*, *Enterobacteriaceae*, and lactic acid bacteria (LAB)	Garcia-Lopez *et al.* (1998); Gill and Newton (1978); Labadie (1999); Russo *et al.* (2006)
Meat products (cured, salted, or fermented)	*Micrococcus*, *Staphylococcus*, *Enterococcus*, and LAB	Cerveny *et al.* (2010); Huis in't Veld (1996); Samelis *et al.* (2000)
Seafood (fresh)	*S. putrefaciens*, *Aeromonas* spp., *Photobacterium phosphoreum*, and *Pseudomonas* spp.	Chai *et al.* (1968); Gram and Huss (1996); Gram *et al.* (2002)
Seafood (processed and salted)	*Brochothrix thermosphacta*, LAB, *Enterobacteriaceae*, and *Vibrio* spp.	Jørgensen *et al.* (2000); Leroi *et al.* (2001)
Refrigerated, raw milk	*Pseudomonas* spp., *Bacillus*, *Micrococcus*, *Aerococcus*, *Lactococcus*, and *Enterobacteriaceae*	Champagne *et al.* (1994); Ledenbach and Marshall (2010)
Ultra-high-temperature milk	*Bacillus* spp.	Stone and Rowlands (1952); Ternstrom *et al.* (1993)
Cheeses	Psychrotrophs, Coliforms, *Clostridium tyrobutyricum*, *Clostridium sporogenes*, *Lactobacillus*, and *Leuconostoc*	Hutkins (2001); Ledenbach and Marshall (2010)
Butter and cream	*Pseudomonas* spp. and Coliforms	Wang and Frank (1981)
Eggs and related products	*Serratia*, *Pseudomonas*, *Proteus*, and *Aerobacter*	Shebuski and Freier (2010)
Vegetables	*Erwinia carotovora*, *Pseudomonas* spp., *Corynebacterium*, *Xanthomonas campestris*, and LAB	Lund (1992); Tournas (2005)
Fruits	*Pseudomonas* spp., *Erwinia*, *Lactobacillus* spp., *Xanthomonas*, and *Acidovorax*	Kalia and Gupta (2007)
Fruit juices	*Alicyclobacillus* spp. and *Propionibacterium* sp.	Smit *et al.* (2011); Walker and Phillips (2007)
Bakery products	*Bacillus* spp.	Voysey and Hammond (1993)
Canned foods	*Thermoanaerobacterium thermosaccharolyticum*, *Moorella thermoacetica*, *Desulfotomaculum nigrificans*, *Clostridium butyricum*, and the facultative anaerobe *Geobacillus stearothermophilus*	Evancho *et al.* (2010)

this deterioration is *Erwinia carotovora*, present in nearly all vegetables (Tournas, 2005) and some fruits (Kalia and Gupta, 2007). However, the intrinsic factors of bakery products limit bacterial growth and favor the prevalence of filamentous fungi as the main spoilage microorganisms (Saranraj and Geetha, 2012). However, bacteria from the genus *Bacillus* spp. may cause a type of spoilage in bread known as ropiness, which is characterized by brown and black stains, release of a rotten fruit odor, and a sticky and moist breadcrumb (Rosenkvist and Hansen, 1995). *Bacillus subtilis* is the main species responsible for this spoilage, but other members of the genus, such as *Bacillus licheniformis* and *Bacillus megaterium*, have also been identified causing this spoilage (Voysey and Hammond, 1993).

Thermal treatment preserves and insures the safety of some types of food, but it also allows specific spoilage microorganisms to prevail in the treated food. In ultra-high-temperature milk, spoilage is caused mainly by spore-forming bacteria of the genus *Bacillus*, which resist thermal treatment and produce enzymes that promote sweet coagulation, gelification, and odor changes (Kalogridou-Vassiliadou, 1992; Ternstrom *et al.*, 1993). *Alicyclobacillus* spp. and *Propionibacterium cyclohexanicum* are the main microorganisms associated with the spoilage of fruit juices that survive thermal treatment and may cause off-flavors, off-odors, discoloration, and turbidity (Smit *et al.*, 2011; Walker and Phillips, 2007). Canned foods submitted to industrial sterilization methods are spoiled exclusively by facultative or strictly anaerobic spore-forming bacteria, such as *G. stearopthermophilus*, *Clostridium sporogenes*, and *Desulfotomaculuns nigrificans*, among others (Evancho *et al.*, 2010).

Yeast spoilage of foods

Yeasts are very important unicellular eukaryotic microorganisms involved in both food and beverage production and spoilage (Querol and Fleet, 2006). These microorganisms spoil foods with high sugar or salt contents, low pH, or other characteristics that give them a competitive advantage over bacteria (Kurtzman, 2006; Smits and Brul, 2005). Most yeasts produce extracellular enzymes, such as proteases, lipases, amylases, and pectinases, and also volatile and nonvolatile

Table 2 Main yeasts involved in the spoilage of specific food groups

Types of food	*Main groups responsible for spoilage*	*References*
Fresh meats	*Candida* spp., *Rhodotorula* spp., *Debaryomyces* spp., *Trichosporon* spp., and *Torulopsis* spp.	Fleet (1992); Osei Abunyewa *et al.* (2000)
Dry and salted meat products	*Debaryomyces hansenii*, *Yarrowia lipolytica*, *Candida*, *Trichosporon*, *Cryptococcus*, and *Rhodotorula*	Dalton *et al.* (1984); Encinas *et al.* (2000); Fleet (1992); Osei Abunyewa *et al.* (2000); Saldanha-da-Gama *et al.* (1997)
Yogurts	*Saccharomyces cerevisiae* and *Hansenula anomala*	Fleet (1990); Hansen and Jakobsen (2003); Rohm *et al.* (1992)
Cheeses	*Candida* spp., *Kluyveromyces marxianus*, *Debaryomyces hansenii*, and *Pichia* spp.	Johnson (2001)
Butter	*Candida parapsilosis*, *Candida zeylanoides*, and *Yarrowia lipolytica*	Lopandic *et al.* (2006)
Fruits and vegetables	*Saccharomyces*, *Candida*, *Zygosaccharomyces*, *Torulopsis*, *Rhodotorula*, *Hansenula*, *Debaryomyces*, and *Pichia* spp.	Jacxsens *et al.* (2001); O'Connor-Shaw *et al.* (1994)
Bakery products	*Saccharomyces*, *Debaryomyces*, *Kluyveromyces*, *Pichia*, *Candida*, and *Zygosaccharomyces*	Van der Zee and Huis in't Veld (1997)
Chocolate, honey, and candy	*Zygosaccharomyces* spp., *S. cerevisiae*, *Torulopsis apicola*, *Hansenula anomala*, and *Kloeckera apiculata*	Thompson (2010)
Carbonated soft drinks	*Saccharomyces* spp., *Zygosaccharomyces* spp., *Torulaspora delbrueckii*, *Pichia anomola*, *Dekkera* spp., and *Candida* spp.	Lawlor *et al.* (2010)

metabolites that affect the sensory characteristics of food, especially flavor and texture. The main genera associated with food spoilage are *Saccharomyces*, *Candida*, *Zygosaccharomyces*, *Debaryomyces*, *Rhodotorula*, and *Pichia* (**Table 2**).

Yeasts play a small part in the spoilage of meats. Despite the competition with bacteria, some yeasts manage to grow on the surface of fresh meats (Nielsen *et al.*, 2008), whereas others may have their growth promoted by changes in intrinsic and extrinsic factors that inhibit bacterial growth (Fleet, 1992; Osei Abunyewa *et al.*, 2000).

Yeasts are also known for their important role in the dairy industry, especially for the production of some fermented products, maturation of some cheeses, and whey fermentation for bioactive compound production (Marth, 1987). However, yeasts are the main cause of yogurt and fermented milk spoilage because the low pH provides a selective environment for their growth. Their presence is associated with off-flavors and gas production (Fleet, 1990; Rohm *et al.*, 1992). These microorganisms also spoil cheeses, and most contamination stems from the brine used in the production process (Kaminarides and Laskos, 1992). Yeasts are normally not involved in butter spoilage, but they have already been detected on spoiled butter (Lopandic *et al.*, 2006).

Yeasts play an important role in the spoilage of fruits and vegetables, especially because of the exposure of these foods to the environment and their minimal processing (Barth *et al.*, 2010). Some of their intrinsic factors, such as pH, also limit bacterial growth. Yeasts are also involved in the deterioration of bakery products, causing white and pink stains or fermenting the carbohydrates, with subsequent production of volatile compounds and alcoholic odor (Legan and Voysey, 1991). In carbonated beverages, the growth of spoilage yeasts is usually characterized by a great production of gas, packaging distension and rupture, abnormal effervescence, excessive turbidity, sedimentation, off-flavors, and off-odors (Lawlor *et al.*, 2010). Osmophilic yeasts, together with xerophilic fungi, are the only microorganisms involved in the spoilage of high-sugar foods with low water activity, such as chocolates, confectionary products, and honey (Thompson, 2010). *Zygossacharomyces bailli* is involved in spoilage of low-pH beverages containing preservatives and high-sugar foods because it has developed mechanisms to adapt these stress factors. These yeasts play a major role in spoilage of beverages, such as fruit juices, soft drinks, chocolate fillings, confectionary creams, etc.

Filamentous fungi spoilage of foods

Filamentous fungi are capable of growing on many different foods, such as grains, meats, milk, fruits, vegetables, seeds, and high-fat products. They are an important group of food spoilage organisms and cause significant economic losses in agriculture and the food industry (Gerez *et al.*, 2013). Spoilage caused by filamentous fungi may manifest as discoloration, off-flavors, loss of structure, loss of texture, formation of visible mycelium, and production of volatile compounds, all of which affect the quality of foods and beverages (Alvo and Raghavan, 1993). These obligate aerobic microorganisms are capable of growing in wide ranges of pH, temperature, and water activity and of using a great variety of substrates as food (Dao and Dantigny, 2011; Sperber, 2010). Filamentous fungi grow more commonly in products with low pH and water activity. They are located mainly on the surface of the food because of their dependence on oxygen. The main food spoilage fungi are *Penicillium*, *Aspergillus*, *Rhizopus*, *Mucor*, *Geotrichum*, *Fusarium*, *Alternaria*, *Cladosporium*, *Eurotium*, and *Byssochlamys* (**Table 3**). Some of these species are also known for their ability to synthesize secondary toxic metabolites called mycotoxins, constituting a problem for agribusiness and the food industry.

Controlling Microbiological Spoilage of Foods

Avoiding or retarding spoilage of raw and processed foods but at the same time preserving the sensory and nutritional

Table 3 Main filamentous fungi involved in the spoilage of specific food groups

Types of food	*Main groups responsible for spoilage*	*References*
Salted fish and similar products	*Wallemia*, *Hortaea*, *Aspergillus*, *Penicillium*, *Polypaecilum*, *Eurotium*, *Basipetospora*, *Cladosporium*, and *Scopulariopsis*	Pitt and Hocking (1999)
Cheeses	*Penicillium*, *Cladosporium*, *Byssochlamys nivea*, *Talaromyces avellaneus*, *Neosartorya fischeri* var. *spinosa*, and *Eupenicillium brefeldianum*	Hocking and Faedo (1992); Pitt and Hocking (1999)
Yogurts	*Penicillium* and *Aspergillus*	Cousin (2001); Ndagijimana *et al.* (2008)
Meat and meat products	*Aspergillus* spp., *Penicillium* spp., *Mucor* spp., *Cladosporium* spp., and *Eurotium* spp.	Deak and Beuchat (1996); Samson *et al.* (2000)
Fruits and vegetables	*Penicillium*, *Phytophthora*, *Alternaria*, *Botrytis*, *Fusarium*, *Cladosporium*, *Phoma*, *Trichoderma*, *Aspergillus*, *Alternaria*, *Rhizopus*, *Aureobasidium*, and *Colletotrichum*	Hagenmaier and Baker (1998); Nguyen-the and Carlin (1994); Tournas (2005)

Table 4 Methods for controlling the microorganisms involved in food spoilage

Principle of preservation	*Methods*
Prevent access of the microorganism to the food	Good agricultural practices Good manufacturing practices Appropriate hygienic and sanitary conditions
Microorganism removal	Washing of surfaces Centrifugation Filtration by membranes
Growth inhibition	Cooling or freezing Reduce water activity (drying and addition of solutes) Food acidification Addition of inhibitors (weak organic acids, nitrites, nitrates, sulfites, and bacteriocins) Microbial competition Atmosphere modification (vacuum or modified atmosphere packaging)
Microbial inactivation	Thermal treatments (pasteurization, sterilization, blanching, and thermization) Radiation High hydrostatic pressures Pulsed electric field processing Ultrasound

characteristics of foods is a great challenge for the industry. The methods used for controlling microbial spoilage include preventing access of the organisms to the foods, removing their cells or spores, inhibiting their growth, and using thermal and nonthermal methods to inactivate them (**Table 4**).

The good manufacturing and handling practices are very important means of reducing the baseline microbial load and increasing shelf life. They are considered the minimum hygienic requirements for the production of any type of food. These practices should be used throughout the entire food production chain, from production of raw materials to consumer consumption.

Other methods of preventing spoilage include: (1) washing the raw materials before processing, which removes microbial cells from its surface, (2) centrifuging, (3) or using membrane filtration processes, which can only be used on certain food groups. In addition to the above-mentioned methods, foods can also be preserved by manipulating factors that not only influence microorganism growth and survival but are also safe for consumers (Gould, 1995). Control of microbial growth by changing intrinsic and extrinsic factors, also called barrier theory, is the main way of reducing food spoilage. The most important barriers used for food preservation are temperature (high and low), low a_w, acidity (pH), redox potential (Eh), preservatives, and other organisms (microbial competition) (Leistner, 2000). These microbial control methods use changes in food characteristics and storage conditions to prevent or reduce microbial growth. Combining different sublethal conditions to prevent microbial growth is a successful approach mainly because it does not change the sensory characteristics of the foods significantly. The great disadvantage of these methods is that microorganisms can resume growth if favorable growth conditions occur.

Some food preservation methods focus on microbial inactivation. They can be classified as thermal or nonthermal methods of food preservation. The thermal methods, such as pasteurization and commercial sterilization, are widely used methods to efficiently inactivate pathogens and reduce the load of spoilage microorganisms. Despite this, they can also change the nutritional and sensory properties of the food. To

replace these methods and meet the increasing consumer demand for healthier products, many nonthermal methods are being developed and used. The main nonthermal methods are radiation, high hydrostatic pressure, pulsed electric field, and ultrasound. Many of these methods are still difficult to implement because of equipment cost, need of trained personnel, and consumer distrust.

Pathogenic Microorganisms in Foods

Gram-positive foodborne pathogens

Most foodborne illnesses are caused by the ingestion of food or water contaminated with microorganisms or their toxic metabolic products. Some Gram-positive bacteria, especially *St. aureus*, *Cl. botulinum*, *Clostridium perfringens*, *Bacillus cereus*, and *L. monocytogenes*, are considered important foodborne pathogens responsible for foodborne illness outbreaks everywhere in the world (**Table 5**). Most of these microorganisms, except for *L. monocytogenes* and *Cl. perfringens*, can grow on food and produce toxins that will cause food poisoning when ingested. *Clostridium botulinum*, *Cl. perfringens*, and *B. cereus* are capable of forming spores, structures that make them resistant to high temperatures and other adverse conditions.

Among Gram-positive bacteria, *St. aureus* stands out because it can grow in foods with high sodium chloride concentrations (10–20%) and low a_w (0.83–0.86). *Staphylococcus aureus* is heat labile and produces heat-resistant enterotoxins (Adams and Moss, 2008). The disease caused by *St. aureus* is due to consumption of animal-origin and excessively handled foods. *Staphylococcus aureus* have a short incubation period and the intoxication caused is self-limiting. The clinical symptoms associated with *B. cereus* poisoning are very similar to those associated with staphylococcal intoxication. However, *B. cereus* can cause two distinct types of foodborne illnesses, namely emetic and diarrheal syndromes. Emetic syndrome is caused by the ingestion of a preformed toxin (cereulide) in foods, which stimulates the vague nerve and causes nausea and vomiting (Agata *et al.*, 2002; Ehling-Schulz *et al.*, 2004). The diarrheic syndrome is an infection caused by ingesting bacterial cells, which then colonize the small intestine and produce enterotoxins *in loco* (Andersson *et al.*, 1998; Clavel *et al.*, 2004). These two syndromes are also characterized by their rapid onset and self-limiting nature, not requiring therapeutic interventions and hospitalization. Despite this, severe and even fatal cases have been reported (Dierick *et al.*, 2005; Granum, 1994; Lund *et al.*, 2000).

Clostridium botulinum, the causative agent of botulism, is a globally distributed bacterium. It causes a severe disease with high mortality rate (Lund and Peck, 2000; Smith and Sugiyama, 1988) due to ingestion of botulinum toxin. Botulinum toxin is preformed in foods and as a neurotoxin, after absorption in the intestines, reaches the nervous system and blocks the release of acetylcholine by nerve terminals (Montecucco *et al.*, 1996). Despite the severity of the illness, the associated neurotoxins are heat labile and can easily be destroyed by heating the food to 80° C for 20 min or 85° C for 5 min (Siegel, 1993).

Clostridium perfringens is another important spore-forming bacterium widely distributed in nature and capable of producing more than 15 toxins that cause different diseases in humans and animals (Lindström *et al.*, 2011). Food poisoning caused by this bacterium is among the most common foodborne illnesses in the world. Food poisoning by *Cl. perfringens* is caused by the ingestion of at least 10^7 cells of the microorganism, which sporulate in the intestines, releasing the *Cl. perfringens* enterotoxin (McClane, 2001).

Differently from the above-mentioned Gram-positive bacteria, *L. monocytogenes* is characterized by its ability to invade intestinal cells and diffuse to other organs and tissues (Orsi *et al.*, 2011). It is a ubiquitous bacterium resistant to desiccation, low water activity, and low pH and may cause anything from a mild gastroenteritis to severe infections of the central nervous system and abortion, depending on the host's susceptibility (Orsi *et al.*, 2011; Rocourt *et al.*, 2003). Listeriosis, the disease caused by *L. monocytogenes*, is a major concern for those involved in food safety because of its high mortality rates (approximately 50%). *Listeria monocytogenes* is a psychrotrophic pathogenic bacterium of very high importance for processed foods or minimally processed foods that are stored for medium to short periods.

Gram-negative foodborne pathogens

Many Gram-negative pathogenic bacteria can cause foodborne illnesses, including *Salmonella* spp., *Campylobacter* spp., pathogenic *Escherichia coli*, *Shigella* spp., *Y. enterocolitica*, *Vibrio* spp., *Aeromonas* spp., and *Cronobacter sakazakii*, among others (**Table 6**).

Among these, *Campylobacter* spp. has been identified as the main cause of foodborne illnesses and outbreaks in the USA and Europe in the past 5 years. The thermophilic species *Campylobacter jejuni* and *Campylobacter coli* are the main causes of campylobacteriosis in humans, a usually self-limiting gastrointestinal disease that can, nevertheless, cause severe complications, such as Guillain–Barré syndrome and reactive arthritis (Allos, 1997; Zilbauer *et al.*, 2008). *Salmonella* spp. also plays an important role in foodborne illness outbreaks worldwide, being an important public health problem (Payment and Riley, 2002). Most serotypes cause gastroenteritis limited to intestinal infections, but the Typhi and Paratyphi serotypes can cause enteric fevers, which are more severe illnesses and affect other organs and tissues (Crump and Mintz, 2010). Although *E. coli* are considered part of the normal intestinal microbiota of warm-blooded humans and animals, some strains can cause foodborne illnesses. These pathogenic strains can be grouped into at least six different groups: enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteroaggregative *E. coli* (EAggEC), diffuse aggregative *E. coli* (DAEC), enterohemorrhagic *E. coli* (also known as verocytotoxin-producing *E. coli*, VTEC, or Shiga toxin-producing *E. coli*, STEC), and enteroaggregative hemorrhagic *E. coli* (EAHEC). Foodborne illness outbreaks have been particularly associated with VTEC and, to a smaller extent, EPEC, ETEC, and EAggEC. A great outbreak with EAHEC strain *E. coli* 0104:H4 occurred in Europe in 2011, with 320 bloody diarrhea cases, 850 cases of hemolytic-uremic syndrome (HUS), and 82 deaths.

Yersinia enterocolitica is one of the most interesting species within the *Yersinia* genus, and related outbreaks are mainly associated with the consumption of contaminated pork.

Table 5 Main Gram-positive bacteria associated with foodborne illnesses

Pathogen	*Characteristics*	*Symptoms*	*Incubation*	*Foods*	*References*
Staphylococcus aureus	Ingestion of one or more types of staphylococcal toxins	Intense vomiting, diarrhea, abdominal pain, and nausea	0.5–6 h	Milk and dairy products, meat products, confectionary products, and ready-to-eat foods	Adams and Moss (2008); Argudín *et al.* (2010); Gilmour and Harvey (1990); Kim *et al.* (2011); Schelin *et al.* (2011); Tranter (1990)
Clostridium botulinum	Ingestion of botulinum neurotoxin	Initial gastrointestinal symptoms, double vision, dry mouth, difficulty in swallowing and controlling tongue, and flaccid paralysis	12–36 h	Canned foods (vegetables and meats), honey, milk products, fish, and fermented seafood	Lindstrom *et al.* (2006); Lund and Peck (2000); Peck *et al.* (2011)
Clostridium perfringens	Release of *Clostridium perfringens* enterotoxin after intestinal sporulation	Acute abdominal pain, nausea, and diarrhea	8–12 h	Meat products and meat-based ready-to-eat foods	Lindström *et al.* (2011); Liu (2009); McClane (2001)
Bacillus cereus	Ingestion of cereulide toxin (emetic syndrome)	Nausea and vomiting	0.5–6h	Rice and grain-based foods	Agata *et al.* (2002); Ehling-Schulz *et al.* (2004); Shaheen *et al.* (2006)
	Toxin production in the small intestine (diarrheic syndrome)	Abdominal pain and aqueous diarrhea	8–16 h	Meats, pasta, desserts, cakes, sauces, and milk	Andersson *et al.* (1998); Clavel *et al.* (2004); Granum (1994)
Listeria monocytogenes	Invasion of intestinal epithelial cells and diffusion to other organs and tissues	Fever, headache, abdominal pain, diarrhea, chills, and complications (abortion, meningitis, and septicemia)	2 days to 3 weeks	Vegetables and salads, cheeses, milk, beef, chicken, and fish	Abadias *et al.* (2008); Cabedo (2008); Caramello and Vaudetti (1990); Kvenberg (1988)

Table 6 Main Gram-negative bacteria associated with foodborne illnesses

Pathogen	*Characteristics*	*Symptoms*	*Incubation*	*Foods*	*References*
Salmonella spp.	Invasion of intestinal cells (gastroenteritis) Typhoid fever (Typhi and Paratyphi serotypes)	Fever, headache, abdominal pain, diarrhea, and chills	12–36 h	Eggs, meats, milk, and dairy products	Crump and Mintz(2010); D'AOUST (2001); Payment and Riley (2002).
Campylobacter spp.	Invasion of intestinal cells	Fever, headache, muscle pain, diarrhea, abdominal pain, and nausea. Complications: Guillain–Barré syndrome and reactive arthritis	2–10 days	Meat and poultry products, raw milk, and contaminated water	Rao *et al.* (2001); Rautelin and Hanninen (2000); Solomon and Hoover (1999); Zilbauer *et al.* (2008)
E. coli (pathogenic) (EPEC, EIEC, EAggEC, ETEC, EHEC, and DAEC)	Adherence to intestinal cells, electrolyte imbalance, toxin production, and rare invasion of intestinal cells	Fever, abdominal pain, chills, diarrhea, and nausea Complications: hemolytic-uremic syndrome (Shiga toxins)	8 h to 4 days	Meats and meat products, milk and milk products, leafy vegetables, and fish	Abadias *et al.* (2008); Atanassova *et al.* (2008); Brandl and Amundson (2008); Eglezos *et al.* (2008)
Shigella spp.	Invasion of intestinal cells and toxin production	Fever, bloody diarrhea, chills, abdominal pain, and vomiting Complications: Hemolytic-uremic syndrome	12–50 h	Shellfish, crustaceans, fruits, vegetables, and salads	Agle *et al.* (2005); Chanachai *et al.* (2008); Kimura *et al.* (2006); Pinu *et al.* (2007); Warren *et al.* (2006)
Yersinia enterocolitica	Invasion of intestinal cells, penetration in mesenteric lymph nodes, and inflammation	Abdominal pain, fever, diarrhea, sore throat, and joint pain	1–3 days	Beef, pork, poultry, oyster, fish, milk, and milk products	Arnold *et al.* (2006); Fredriksson-Ahomaa *et al.* (2007); Yucel and Ulusoy (2006)
Vibrio cholerae	Cholera toxin production in the small intestine	Abdominal pain, aqueous diarrhea, and dehydration	6 h to 5 days	Contaminated water, vegetables, and seafood	Austin (2010)
Vibrio parahaemolyticus	Colonization of the small intestine and production of adhesins and cytotoxins	Abdominal pain, diarrhea, colic, fever, headache, nausea, vomiting, and chills	4 h to 4 days	Shellfish, raw fish, shrimp, and oyster	Chan and Chan (2008); Davis *et al.* (2007); DePaola *et al.* (2003)
Vibrio vulnificus	Colonization of the small intestine and production of adhesins and cytotoxins	Diarrhea, abdominal pain, vomiting, fever, and may cause infections in wounds	7 h to some days	Shrimp, fish, oysters, and mussels	Colakoglu *et al.* (2006); Gopal *et al.* (2005); Jung *et al.* (2007)
Cronobacter sakazakii	Opportunistic infection	Abdominal pain and bloody diarrhea Complications: septicemia, meningitis, and brain abscess		Infant foods and formulas	Strydom *et al.* (2012); Zhou *et al.* (2008)
Aeromonas spp.	Opportunistic infection	Symptoms similar to those of cholera with aqueous diarrhea and mild fever; in some cases, symptoms similar to dysentery with bloody diarrhea, fever, and abdominal pain		Fish, shrimp, milk, and bottled water	Igbinosa *et al.* (2012)

Shigella spp. are transmitted by the fecal/oral route and ingestion of contaminated food or water. These bacteria are highly infectious and can produce the Shiga toxin, which causes the HUS (DuPont *et al.*, 1989). *Vibrio cholerae*, *Vibrio vulnificus*, and *Vibrio parahaemolyticus* have been associated with foodborne illnesses due to consumption of contaminated water, vegetables, and seafood (DePaola *et al.*, 2003; Drake *et al.*, 2007; Morris, 2003).

Other Gram-negative bacteria, such as *Aeromonas* spp. and *Cr. sakazakii*, are considered opportunistic foodborne pathogens and infect specific population groups, namely newborns, the elderly, and immunocompromised individuals (Igbinosa *et al.*, 2012; Nazarowec-White and Farber, 1997).

Protozoan foodborne pathogens

Protozoans are important etiological agents of human diseases that can be transmitted by contaminated water and foods. Intestinal infections caused by protozoans include toxoplasmosis (*Toxoplasma gondii*), cryptosporidiosis (*Cryptosporidium* sp.), cyclosporiasis (*Cyclospora cayetanensis*), cystoisosporiasis (*Cystoisospora belli*), sarcocystosis (*Sarcocystis* sp.), giardiasis (Giardia sp.), and amebiasis (*Entamoeba histolytica*). More recently, *Trypanosoma cruzi*, the causative agent of Chagas disease, was included in this list because it can be transmitted by foods (Yoshida *et al.*, 2011). Among the abovementioned protozoans, *Giardia*, *Cryptosporidium*, and *Cyclospora* are the main microorganisms responsible for diarrhea in humans (Dawson, 2005). The main transmission route of these protozoans is the fecal/oral route. However, indirect transmission from pets, such as dogs and cats, and ingestion of foods contaminated with oocysts represent a threat (Karanis *et al.*, 2007; Smith *et al.*, 2007). In general, water and certain foods, such as vegetables, fruits, and seafood, which are more likely to have been in contact with diseased individuals, are the main vehicles of intestinal protozoans.

Foodborne viruses

Viruses are small intracellular parasites capable of causing diseases in plants, animals, and human beings. Many viruses can be found in the human intestines, but only some are generally recognized as important foodborne pathogens (Koopmans and Duizer, 2004). Foodborne viruses attack intestinal cells and propagate within them. Later, some types of viruses may attack other cells or invade other organs, such as the liver and the central nervous system (Bajolet and Chippaux-Hyppolite, 1998; Koopmans and Duizer, 2004). The main genera associated with foodborne illnesses are Norovirus, Sapovirus, Enterovirus, Hepatovirus, Astrovirus, Rotavirus, and members of the Adenoviridae family, among others (Vasickova *et al.*, 2005). Norovirus, Rotavirus, and the hepatitis A virus are the ones most related with foodborne illness outbreaks around the world. All these viruses can be transmitted through the fecal/oral route, either by direct contact with infected individuals or by ingestion of contaminated water and foods, such as vegetables, fruits, shellfish, bivalve molluscs, and sometimes beef (Dubois *et al.*, 2002; Keeffe, 2004; Koopmans and Duizer, 2004; Lees, 2000; Richards, 2001).

Although viruses are the most common pathogenic foodborne agents, their identification and association with foods is still difficult in the absence of systematic surveillance and appropriate legislation to establish food safety criteria (Koopmans and Duizer, 2004).

Mycotoxigenic molds

Filamentous fungi can grow in foods and cause chronic disease in humans and animals because of their mycotoxins. Mycotoxins are secondary metabolites that may cause a variety of adverse effects in human beings, such as intestinal symptoms, allergic responses, immunosuppression, mutagenesis, inhibition of protein synthesis and essential metabolic pathways, and cancer (Bennett and Klich, 2003). Mycotoxins may be produced before harvest or during storage, and filamentous fungi need favorable water activity, atmosphere (oxygen), substrates, and temperatures to grow. The main filamentous fungal genera associated with the production of mycotoxins in foods are *Aspergillus* spp., *Penicillium* spp., and *Fusarium* spp.

Aspergillus flavus and *Aspergillus parasiticus* are the main fungi responsible for the production of aflatoxin in peanuts, corn, wheat, rice, and other grains. The main types of toxins isolated from these foods are aflatoxins B_1, B_2, G_1, and G_2. They are characterized by their fluorescence under ultraviolet light. Additionally, toxic metabolites, such as aflatoxins M_1 and M_2, may be present in the flesh and milk of animals fed grains contaminated with type B aflatoxin.

Aspergillus carbonarius, *Aspergillus niger*, *Aspergillus ochraceus*, and *Penicillium verrucosum* are associated with the production of ochratoxins. An important characteristic of this mycotoxin is that it is found in many different products, such as raisins, barley, soybean and coffee products, grapes, and wines, but usually in low levels. These mycotoxins can accumulate in human or animal body tissues and fluids when contaminated foods are consumed regularly.

Citrinin is another mycotoxin produced by *Penicillium citrinum* and by some *Aspergillus* species, such as *Aspergillus terreus* and *Aspergillus niveus*, and industrially important species, such as *Monascus ruber*, *Monascus purpureus*, *Penicillium Camemberti*, and *Aspergillus oryzae*. This nephrotoxic mycotoxin is found mainly in wheat, oat, rye, corn, barley, and rice. Patulin, produced by some species of *Penicillium*, *Aspergillus*, and *Byssochlamys*, is the main mycotoxin found in fruits, such as apple, pear, and cherry, and their derivatives. This toxin may irritate the stomach and cause vomiting and nausea.

Fusarium spp. species are responsible for the production of many mycotoxins, such as fumonisins, zearalenone, and trichothecenes (deoxynivalenol, also known as vomitoxin or DON, and toxin T2); corn is the source of these mycotoxins.

The toxic effects and economic losses caused by mycotoxins are of global concern for public health and agricultural and livestock production. Mycotoxin control should be done in the entire food production chain, taking into account the interactions between toxicogenic fungi and plants, storage manner and conditions, animal contamination and metabolism, detection methods, and mycotoxin elimination from foods.

Controlling and Inactivating Foodborne Pathogens in Foods

Diverse strategies have been used to control and inactivate foodborne pathogens. These methods are used for insuring

that foods are pathogen free or for keeping them within levels that do not jeopardize consumer's health.

Most animal-origin pathogens are transmitted by the oral/fecal route, and good manufacturing practices and hygienic conditions throughout the entire food production chain can reduce the risks of contamination effectively. Use of potable water, prohibition of animals in processing units, pest control, correct hygiene practices by food handlers, and proper hygienic and sanitary conditions are important for reducing the contamination of foods by pathogenic protozoans and intestinal viruses.

Some pathogenic bacteria depend on favorable conditions to grow on foods and produce enough toxins to cause foodborne illness. The inhibition of microbial growth by changing intrinsic and extrinsic factors, especially temperature, water activity, and pH, are ways of reducing foodborne illnesses caused by these bacteria.

Foodborne pathogens have different virulence levels. Sometimes a few pathogenic cells are capable of causing disease, so their elimination is essential for food safety. Among all inactivation methods, heat can be considered the most commonly used. However, consumers' demand for minimally processed foods and essentially unchanged nutritional and sensory characteristics requires nonthermal methods of microbial inactivation. Some of these methods are irradiation, high hydrostatic pressure, pulsed electric field, and ultrasound. However, more studies are required to determine how efficiently these methods can be used in industrial scale, not only to insure inactivation of specific microbial groups but also to minimize losses on the food components and be accepted by consumers.

Technological microorganisms in foods

Microorganisms of industrial importance

Biotechnology is defined as the use of live organisms or biological systems in industrial processes and waste treatment plants (Borem *et al.*, 2003). Today, biotechnology is equally important in food science and technology. Fermentation processes are a link between the old food preparation arts (cheese and wine, among others) that use natural microbiota and the modern food fermentation industry.

There are two types of cells in nature and both types are used in industrial fermentation processes: prokaryotes (bacterial cells) and eukaryotes (fungal, animal, and plant cells). Industrial microorganisms also differ as a function of their oxygen requirement: they may be strictly aerobic, such as *Streptomyces* and most filamentous fungi; strictly anaerobic, such as clostridiums; and facultative, such as industrial yeasts.

The bacteria used in fermentation processes are mainly chemoorganotrophic, that is, they obtain their energy by oxidizing organic compounds. Lactobacilli are bacteria that ferment carbohydrates, producing lactic acid. They can be homo- or heterofermentative. Homofermentative species produce only lactic acid from glucose, whereas heterofermentative species produce ethanol, carbon dioxide, and lactic acid from glucose.

The ability to ferment carbohydrates makes lactobacilli very useful for food production, but they may also cause food spoilage. However, Streptococci, Pediococci, and Lactococci are Gram positive, homofermentative cocci that produce mainly lactic acid. Then, these genera have a major importance for industrial processes.

Molds are also chemoorganotrophic and the most important molds used in industrial fermentation are classified into two groups: (1) Zygomycota, which have nonseptate hyphae and include the genera *Mucor* and *Rhizopus* and (2) Deuteromycota, which have septate hyphae and include the genera *Trichoderma*, *Aspergillus*, *Penicillium*, *Fusarium*, and *Aureobasidium*. Some *Mucor* and *Rhizopus* species are used for the production of cheeses and fermented Eastern foods. Among the Penicillia, *P. camemberti* and *Penicillium roqueforti* stand out because they are used for producing the Camembert and Roquefort cheeses, respectively.

Yeasts are unicellular fungi that reproduce asexually or sexually. The most commonly used yeasts in industrial fermentation processes are the *Saccharomyces*, with the most important species being *Saccharomyces cerevisiae*. *Saccharomyces cerevisiae* is used for many different purposes, such as the production of breads, beverages (beers and wines, among others), alcohol, and glycerol, among other uses in technological processes. *Saccharomyces cerevisiae* does not break down lactose, so the production of alcohol and biomass from whey requires another species, such as *Kluyveromyces lactis*. *Kluyveromyces lactis* has the necessary enzymes to break down lactose. Other important yeasts are: *Candida utilis*, used for processing apple residues (Fellows and Worgan, 1987), and *Endomycopsis fibuligera*, used for ethanol production (Reddy and Basappa, 1996; Chi *et al.*, 2009).

Biotechnological use of lactic acid bacteria in food production

LAB are found in very diverse environments, such as fermented foods and beverages, plants, fruits, soil, and residual water. They are also part of the respiratory and intestinal tracts of humans and other animals (Holzapfel and Wood, 1995).

The manufacturing of fermented meat products intends to continue using a set of microorganisms because they give the product agreeable sensory, hygienic, and sanitary characteristics. This set of LAB are introduced into the product by raw materials or by starter cultures sold frozen or freeze-dried (Patarata, 2002).

From the technological perspective, LAB have many potential uses ranging from control of the fermentation process in the production of fermented foods to their use as probiotics for human and animal health Inês *et al.*, 2008. According to Klaenhammer *et al.* (2002), the main beneficial and nonpathogenic genera used by the food industry are: *Lactococcus* (milk), *Lactobacillus* (milk, meat, vegetables, and grains), *Leuconostoc* (vegetables and milk), *Pediococcus* (vegetables and meat), *Oenococcus oeni* (wine), and *Streptococcus thermophilus* (milk). These microorganisms are generally regarded as safe (GRAS), although some studies in the literature have shown that some strains become opportunistic pathogens in individuals with a weakened immune system Zé-Zé *et al.* (2004).

LAB cultures are an important group of starter cultures used by the food industry for the production of cheeses, yogurts, sausages, sauerkraut, and sourdough (Messens and De Vuyst, 2002). Starter cultures quickly acidify the raw materials and give the final products pleasant sensory characteristics (Leroy *et al.*, 2006).

The quick acidification promoted by LAB prevents the development of other microorganisms that could give the final product undesirable characteristics (Hugas and Monfort, 1997). This inhibitory activity stems from their ability to produce lactic and acetic acids, hydrogen peroxide, bacteriocins, and surfactants (Fernández *et al.*, 2000).

Other microorganisms in this group include the probiotics. The probiotics are defined as "live organisms that, when administered in adequate amounts, confer a health benefit on the host" (Guarner and Schaafsma, 1998). LAB are the most common microorganisms used as probiotics (Cinque *et al.*, 2010).

Within the *Lactobacillus* genus, the most studied strains used as probiotics are *Lactobacillus acidophilus* LA1, *L. acidophilus* NCFB 1748, *Lactobacillus rhamnosus* GG, *Lactobacillus casei shirota*, *Lactobacillus gasseri* ADH, and *Lactobacillus reuteri*. They boost the immune system, help to control pathogenic microorganisms in the intestines by competitive exclusion, and have anticarcinogenic activity Leroy and De Vuyst, 2004. The genus *Bifidobacterium*, including *Bifidobacterium breve*, *Bifidobacterium longum* BB536, and *Bifidobacterium lactis* Bb12, also promotes good intestinal function. These microorganisms reduce intestinal irritation and can be used in the treatment of allergies, improvement of diarrhea caused by rotavirus, and reduction of the incidence of traveler's diarrhea (Ouwehand *et al.*, 2002).

The use of probiotics in animal feed has also been studied (Corcionivoschi *et al.*, 2010). The advantages include the improvement of intestinal disorders, inhibition of pathogenic bacteria, and proliferative stimulation of peripheral blood mononuclear cells (Collado *et al.*, 2007; Schierack *et al.*, 2009; Strompfova *et al.*, 2006). Hence, their use in livestock feed is increasingly desirable because they may dispense with the need of some antibiotics or other pharmaceutical products.

Biotechnological use of acetic acid bacteria in food production

The production of vinegar from alcohol–water solutions has been known for at least 10 000 years since Romans and Greeks obtained vinegar by the spontaneous fermentation of wine exposed to air (Crueger and Crueger, 1989). The process consists of the production of acetic acid.

The oxidation of ethanol into acetic acid is done by a mixed culture of acetic bacteria, preferably, a mixed microbiota of *Acetobacter* with different species or strains of the same species Zancanaro, 2001. However, different *Gluconobacter* and *Frateuria* strains are normally found in the microbiota used by vinegar manufacturers (Ebner *et al.*, 1996).

Although the classification of acetic acid bacteria is very problematic (Ebner *et al.*, 1996), it is estimated that mainly 20 strains of the species *Acetobacter aceti*, *Acetobacter pasteurianus*, *Acetobacter acidophilum*, *Acetobacter polyoxogenes*, *Acetobacter hansenii*, and *Acetobacter liquefaciens* are responsible for submerged acetification in the food industry Zancanaro, 2001.

Vinegars are classified according to the raw materials used in their preparation. For example, distilled vinegar is obtained by the acetification of diluted and distilled alcohol. Wine vinegar is obtained by the acetification of grape wine (Ebner *et al.*, 1996). Nondistilled alcohol–water solutions (fruit wines, grain wines, and others) do not require the addition of nutrients for acetification. These solutions already contain the nutrients required by acetic acid bacteria, as the preceding alcoholic fermentation helped to enrich them. However, the acetification of alcohol–water solutions prepared with distilled alcohol (ethanol or distilled beverages) requires the addition of many nutrients, namely glucose and dietary minerals, including ammonium phosphate (Ebner *et al.*, 1996; Zancanaro, 2001). Finally, if the solution requires dilution, the added water should be potable, of low hardness, and free from sediments and chlorine (Zancanaro, 2001).

Acetic acid bacteria are obligate aerobes. Interruption of aeration during any phase of the submerged fermentation process may impair vinegar production. The degree of impairment increases as the duration of the interruption and the total concentration of ethanol and acetic acid increase. For example, a 2 min aeration interruption in a solution with a total concentration of 5% causes a loss of 34% of the viable cells; the same loss occurs after a 10–20 s aeration interruption in a solution with a total concentration of 12% (Crueger and Crueger, 1989; Ebner *et al.*, 1996).

Additionally, once there is no more ethanol in the solution, acetic acid may be oxidized to CO_2 and H_2O depending on the organisms present in the solution (Ebner *et al.*, 1996). When ethanol reaches a critical concentration of 0.2%, the semicontinuous process must be stopped (Crueger and Crueger, 1989).

Biotechnological use of yeasts and molds in food production

Yeasts are used for processing numerous basic food items. Bread texture is given by the activity of the yeast *Sa. cerevisiae*, which ferments small amounts of sugar and releases carbon dioxide, forming bubbles. The production of beer also depends on yeasts. Beer is a malt beverage resulting from the alcoholic fermentation of an aqueous extract of malted barley and hops. Consequently, beer production is a multiple-stage process involving the biological conversion of fresh raw materials into a final product (Walker, 2000). All traditional brewing yeasts used in beer production consist of *Sa. cerevisiae* strains, which are a diverse group of microorganisms.

Still on beverages, sparkling wines are other gastronomic inventions produced by fungi. Nowadays, most wine is produced industrially by selected *Saccharomyces* sp. strains, and small wineries even select yeasts from their own environment as starter cultures (Ortiz *et al.*, 2013). The selected strains must have the following characteristics: ethanol tolerance, high fermentation activity, ability to grow in the presence of high sugar concentrations, and resistance to certain fermentation by-products (Nikolaou *et al.*, 2006). Even when strains meet these criteria, the starter culture may fail because of the presence of wild yeasts (Capece *et al.*, 2010).

Cheeses also deserve to be highlighted in addition to the above-mentioned products. They have probably been consumed by humans since the domestication of animals because they are an efficient means of storing milk proteins for long periods of time. There are more than 500 different types of cheeses, each one bearing specific characteristics of the location they were originally produced. However, only some cheeses are produced by fungi and these happen to be those with the most appreciated flavor and texture. These cheeses are divided into two categories: Camembert-type cheeses and blue Roquefort-type cheeses. The former includes the world-famous

Camembert and Brie and the less known cheeses Troyes, Thenay, and Vendome. These cheeses are produced by two *Penicillium* species: *camemberti* and *caseiolum* (hyphomycetes).

However, the blue cheeses, namely Roquefort, Stilton, Gorgonzola, Danish Blue, and Wensleydale, are produced with *P. roqueforti*. This fungus oxidizes fatty acids into methyl ketones, producing unique flavors and odors.

Many Asian countries developed a wide range of foods and condiments fermented by fungi. The most widely known fermented Asian food item is undoubtedly shoyu, a Japanese sauce made by fermenting soybeans with *A. oryzae*. Another important Japanese product is miso, a fine paste produced by fermenting soybeans and rice or barley. The fungi used for producing miso are *Saccharomyces rouxii* and *A. oryzae* (Abe *et al.*, 2006).

Assessing the Microbiological Quality and Safety of Foods

Microbiological Sampling Plans

The International Commission on Microbiological Specifications for Foods (ICMSF) has provided guidance on the use of sampling plans and microbiological criteria for international food trade for many decades. Many microbiological criteria have been established by the ICMSF and national surveillance and public health authorities. These criteria may be important in food analysis, including the analysis of raw materials and ingredients of unknown origin. Microbiological criteria are an important part of the food protection and public health systems, and they assist in determining whether foods meet required safety needs.

Two types of sampling plans, by attribute and by variable, are used for performing microbiological analysis and making decisions on food safety and quality (ICMSF, 1986). Attribute sampling plans assess data quality and detect the occurrence of changes, without determining their degree, i.e., they provide a qualitative assessment. However, variable sampling plans assess quality characteristics quantitatively by making measurements.

Variable sampling can be used when the numbers of microorganisms in the food follow a log-normal distribution. The implementation of such a plan requires making many decisions. The first decision regards the establishment of an acceptable limit for the microbiological quality of the study lot and a maximum proportion of the lot that may exceed said limit. Furthermore, an α (standard deviation of the log-normal distribution) should be chosen to represent the maximum probability of accepting the nonconformity of the lot, so 1α is the desired probability for rejecting the nonconformity of the lot (Schothorst *et al.*, 2009). The disadvantages of this plan include the calculations required for lot assessment and for each variable and the fact that the probability distribution of each measurement must be known or assumed. The transformation that insures a normal distribution may not be known, and the estimates of variance are often different for each measurement. For these reasons, variable sampling plans are not widely used in the food industry for microbiological measurement (Midura and Bryant, 2001).

Attribute sampling plans are used when the microbiological distribution in the food is unknown or when the counts of microorganisms do not follow a log-normal distribution (Forsythe, 2000). The ICMSF describes two attribute sampling plans (ICMSF, 1986): a two-class plan and a three-class plan (**Figure 1**). The two-class plan consists of specifying *n*, *m* and *c*, where *n* is the number of units sampled from a lot, *m* is the maximum acceptable number of microorganisms per gram, and *c* is the maximum number of units that may exceed *m* (the lot is rejected if *c* is exceeded).

A sampling plan may approve a relatively bad lot of food and reject a good lot. This can be illustrated by the operating characteristic curve (OC) (**Figure 2**), where the probability of acceptance on the *y*-axis is the expected proportion of times that a lot with a certain quality is accepted, and the proportion of defective sampled units of the lot is on the *x*-axis.

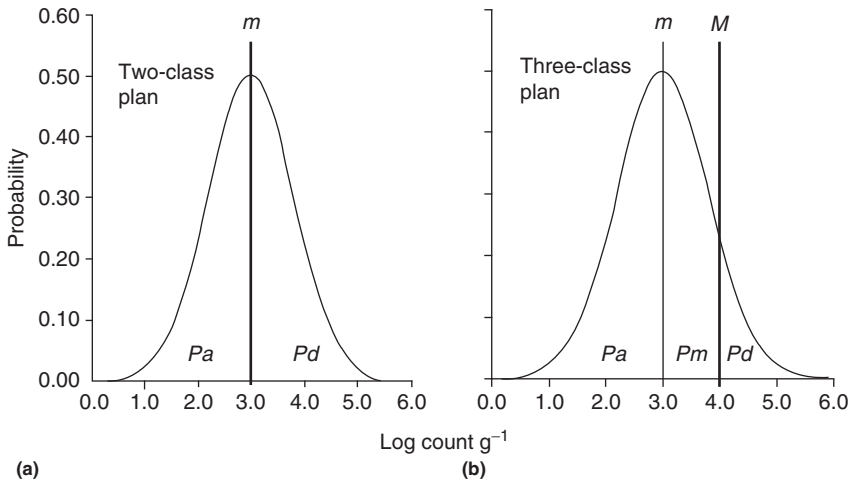

Figure 1 The relationships between acceptable and defective log concentrations for a two-class plan and acceptable and defective concentrations for a three-class plan when $m=3.0$, $M=4.0$, and distribution of organisms has mean$=3.0$ and $\sigma=0.8$. *Pa* is the proportion of acceptable material, *Pm* is the proportion marginally acceptable, *Pd* is the proportion defective, *m* is the maximum acceptable number of microorganisms per gram, and *M* is the upper bound on the marginally acceptable concentration. Adapted from Legan, J.D., Vandeven, M.H., Dahms, S., Cole, M.B., 2001. Determinig the concentration of microrganisms controlled by attributes sampling plans. Food Control 12, 137–147.

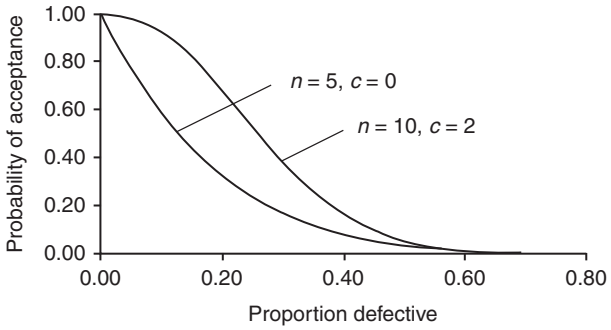

Figure 2 Operating characteristic curves showing the probability of acceptance at different defect rates for two-class plans with $n=10$, $c=2$ and $n=5$, $c=0$. n is the number of units sampled from a lot and c is the maximum number of units that may exceed m. Adapted from Legan, J.D., Vandeven, M.H., Dahms, S., Cole, M.B., 2001. Determinig the concentration of microrganisms controlled by attributes sampling plans. Food Control 12, 137–147.

The ability of a sampling plan to reject or approve the quality of a lot with high probability and the slope of the OC curve depend on n and c. **Figure 2** shows how much these characteristics change when the number of samples increases from 5 to 10 units, resulting in steeper curves and lower probabilities of acceptance, which provides better assurance that lots with high proportion defectives will be rejected (Dahms, 2004).

Three-class plans have an additional parameter called M, which is an amount chosen to distinguish marginally acceptable from unacceptable counts. Any sample with a count greater than M is rejected (**Figure 1**). Hence, a three-class plan is that in which the food may be divided into three classes according to its microbial load (Forsythe, 2010). The sample is acceptable if the counts are below m; marginally acceptable if the counts are greater than m but below M; and rejected if the counts exceed M. The strictness of a sampling plan should be given by the potential hazard of the food or its desired condition by the time it is consumed (ICMSF, 1986).

Overview of Microbiological Methods for Food Analysis

The microbiological analysis of food is part of food safety management and conformity tests that define microbiological criteria or assess the performance of control strategies based on the Hazard Analysis and Critical Control Point.

For microbiological testing of foods, rapid and conventional methods can be used. The conventional methods are called so because they were developed many years ago and have been in use ever since as the official methods of most food microbiology laboratories. These methods are described in the so-called reference publications; they are accepted internationally and recommended, for example, by the American Public Health Association, ICMSF, and the Food and Drug Administration.

The traditional methods have disadvantages associated with excessive laboratory work, time consumption, culture media, and laboratory glassware requirement. Other limitations should also be taken into account, such as technique failures related to high agar temperature and high risk of contamination because of all the stages involved in culture medium preparation and inoculation (Chain and Fung, 1991). The limitations of the traditional methods have encouraged the development of alternative methods for microbiological analysis of foods.

Many techniques for enumerating and identifying bacteria have been studied; they are currently called rapid methods. A rapid method can be defined as any method or system that reduces the time required for obtaining a microbiological test result (Feng, 1996). These include enumeration methods (quantitative methods) and detection methods (qualitative methods), which can be used depending on the objective of the study.

The direct epifluorescent filter technique consists of a rapid way of enumerating viable and unviable microorganisms using microscopy. The sample is pretreated with enzymes and surfactants and filtered with a polycarbonate membrane that traps microorganisms. Detection can be automated by connecting the microscope to an image analysis system (Jasson *et al.*, 2010). Enumeration takes 0.5–1.0 h, but the pretreatment stage may increase the total time required for analysis. The detection limit is 10^4–10^5 cells per ml. This technique has been used to enumerate bacteria in raw milk (Moran *et al.*, 1991; Rosmini *et al.*, 2004) and minimally processed vegetables (Araújo *et al.*, 2009).

Another microscope-related technique is flow cytometry, a powerful technique that uses light scattering for rapidly analyzing cells suspended in a fluid. Flow cytometry measures the optical characteristics of cells. Because most microorganisms are optically very similar, fluorescent stains may be used for verifying the microorganism's viability and their metabolic status (Flint *et al.*, 2006). This technique has been used for monitoring the load of somatic cells in milk (Gunasekera *et al.*, 2003), in wine (Malacrino *et al.*, 2001), and for assessing the microbiological quality of water (Delgado-Viscogliosi *et al.*, 2005).

Another rapid technique developed is the adenosine triphosphate (ATP) bioluminescence assay. This technique measures the light emitted by ATP when ATP reacts with luciferin and oxygen in the presence of the enzyme luciferase and magnesium cations. The amount of light produced (measured as relative light units) is proportional to ATP concentration, and consequently, to the number of microorganisms present in the sample. This technique can be used only if the microbial load is high ($>10\,000$ colony-forming units per gram, CFU g^{-1}). ATP is found not only in bacterial cells but also in any biological material, so ATP bioluminescence is generally used as a rapid indicator of organic load (Jasson *et al.*, 2010). The ATP bioluminescence assay has been used to determine the microbiological quality of food products, such as milk and dairy products, beverages, vegetables, meats, and meat products; to assess the water quality of the public water supply system; and to assess the efficiency of the cleaning and disinfection processes used by the food and pharmaceutical industries and by hospitals (Corbitt *et al.*, 2000; Griffiths *et al.*, 2000; Kennedy and Oblinger, 1985; Velazquez and Feirtag, 1997; Tydrich, 1996).

Classical or modified culture methods and molecular methods, such as enzyme-linked immunosorbent assay

(ELISA), enzyme-linked fluorescent assay (ELFA), fluorescence *in situ* hybridization (FISH), and conventional, real-time, and multiplex polymerase chain reaction, have been developed for detection of foodborne microorganisms. Classical methods are usually used for detecting pathogens in 25 g food samples. These methods require preenrichment stages because pathogens may have been injured in the study food (Wu, 2008; Jasson *et al.*, 2010). Later, other tests are used for confirming the findings.

ELISA is a biochemical technique based on antibody–antigen interaction. Detection may take from 2 to 3 h (Kumar *et al.*, 2008). ELFA is an automated test of the Bio-Mérieux's VIDAS® system that combines immunoenzymatic assay with fluorescence detection. A VIDAS® run may take from 25 to 120 min, depending on the target microorganism (Sewell *et al.*, 2003).

Molecular methods for the detection of bacteria in food, such as FISH, and multiplex and real-time PCR have also been developed and applied in microbiological analysis. FISH uses fluorescent probes to detect small deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) sequences. These probes consist of nucleotide sequences that complement the DNA or RNA sequences; they are designed to identify (Shimizu *et al.*, 2009).

PCR is a rapid, inexpensive, and safe technique based on the exponential amplification of a specific DNA region. This technique has revolutionized the scientific world and its uses are innumerous. PCR success is explained by its ability to amplify a specific DNA sequence and its simplicity, accuracy, high sensitivity, and high specificity. Owing to PCR specificity given by primers, DNA does not need to be isolated even if the DNAs from other species are present. PCR limitations include the synthesis of specific primers requires knowing the DNA sequence of their target region; PCR sensitivity allows it to detect the presence of DNA contamination, inducing incorrect results; the length of the target sequence cannot exceed 5 kb, because it is difficult to use PCR to amplify longer sequences; and incorrect bases may be incorporated into a strand.

Today there are techniques faster than PCR, such as the Bax System, which consists of automated, real-time PCR for the detection of *Salmonella*, *E. coli* 0157:H7, *L. monocytogenes*, *Listeria* spp., *Cr. sakazakii*, *Ca. jejuni*, and *Ca. coli* and some molds and yeasts. The Bax System can perform as many as 96 simultaneous analyses and an analysis takes approximately 3.5 h. This technique assesses the unique genetic structure of the microorganism, greatly increasing the sensitivity and specificity of the method (Yuste and Fung, 2007).

Other innovative techniques for the microbiological analysis of food are being tested, such as microarrays (DNA microchip). This technique consists of the hybridization of messenger RNAs (mRNA) on a surface containing millions of attached sequences of DNA. It is used for specific gene identification, genome comparison, and monitoring of gene expression (Jasson *et al.*, 2010; Ikeda *et al.*, 2006).

Biosensors are another innovative technique that may be used for detecting foodborne pathogens. They consist of biologically active material, such as enzymes, antibodies, antigens, or nucleic acids, attached to a surface. Biosensors reduce the time required for analysis and can be used for analyzing very small samples (Zhang *et al.*, 2009).

Food Packaging

GL Robertson, University of Queensland, Brisbane, Australia

© 2014 Elsevier Inc. All rights reserved.

Introduction

Food packaging lies at the very heart of the modern food industry and very few foods are sold unpackaged. Good packaging prevents waste and ensures that the food retains its desired quality throughout its shelf life. Despite its importance and the key role that packaging plays, it is often regarded as, at best, somewhat superfluous, and, at worst, a serious waste of resources and an environmental menace. Such views arise because, by the time most consumers come into contact with a package, its job, in many cases, is almost over. However, if the world is ever going to be able to feed 9 billion people, then the quality and quantity of food packaging is going to have to increase considerably.

Requirements of Packaging Materials

Four primary, interconnected functions of packaging have been identified: containment, protection, convenience, and communication (Robertson, 2013). Foods must be contained before they can be moved from one place to another, and the package must contain the product to function successfully. Without containment, product loss and pollution would be widespread.

Protection is often regarded as the primary function of the package: to protect its contents from outside environmental influences such as water, water vapor, gases, odors, microorganisms, dust, shocks, vibrations, and compressive forces. For the majority of foods, the protection afforded by the package is an essential part of the preservation process. For example, aseptically packaged milk and fruit juices in paperboard laminate cartons only remain aseptic for as long as the package provides protection. Likewise, vacuum-packaged meat will not achieve its desired shelf life if the package permits O_2 to enter, and dried foods will deteriorate if the package permits moisture to enter.

Modern industrialized societies have brought about tremendous changes in life styles and created a demand for greater convenience in household products; the packaging industry has had to respond to those changes. Products designed to increase convenience include foods that are preprepared and can be cooked or reheated in a microwave oven, preferably without removing them from their package, and special kinds of packages with dispensing caps, sprays, and other convenience features make products easier to use.

Two other aspects of convenience are important in package design. One of these can best be described as the apportionment function of packaging. The relative cheapness of food is largely because of its production on an enormous scale, leading to the need for effective methods of apportioning the product into consumer-sized dimensions. For a product that is not entirely consumed when the package is first opened, the package should be resealable and retain the quality of the product until completely used.

An associated aspect is the shape (relative proportions) of the primary package with regard to consumer convenience (e.g., easy to hold, open, and pour as appropriate) and efficiency in building into secondary and tertiary packages.

The modern methods of consumer marketing would fail were it not for the messages communicated by the package. The ability of consumers to instantly recognize products through distinctive shapes, branding, and labeling enables supermarkets to function on a self-service basis. By allowing brands to be created and standardized, it makes advertising meaningful and large-scale distribution possible. Other communication functions of the package include a universal product code (UPC) that can be read accurately and rapidly, serving instructions, and nutritional information on the outside of the package.

Packaging Materials

The protection offered by a package is determined by the nature of the packaging material and the format or type of package construction. A wide variety of materials is used in packaging and primary packaging materials consist of one or more of the following materials: glass, metals, paper, and plastic polymers (Robertson, 2013). These are briefly described below.

Glass

Glass is an amorphous, inorganic product of fusion that has been cooled to a rigid condition without crystallizing. Although rigid, glass is a highly viscous liquid that exists in a vitreous or glassy state. A typical formula for soda-lime glass is:

- silica, SiO_2 68–73%
- calcia, CaO 10–13%
- soda, Na_2O 12–15%
- alumina, Al_2O_3 1.5–2%
- iron oxides, FeO 0.05–0.25%

The loss on ignition or fusion loss (generally the oxides of carbon and sulfur) can vary from 7% to 15%, depending on the quantity of cullet (used and scrap glass), there being less fusion loss the greater the quantity of cullet. Soda-lime glass accounts for nearly 90% of all glass produced and is used for the manufacture of containers where exceptional chemical durability and heat resistance are not required.

The two main types of glass containers used in food packaging are bottles (which have narrow necks) and jars (which have wide mouths or openings). Approximately 75% of all glass food containers are bottles and approximately 80% of container glass is clear, the remainder being mainly amber or green. Today's glass containers are lighter but stronger than their predecessors, and through such developments the glass container has remained competitive and

 doi:10.1016/B978-0-444-52512-3.00063-2

continues to play a significant although declining role in the packaging of foods.

The container finish (so-called because in the early days of glass manufacturing, it was the part of the container fabricated last), is the glass surrounding the opening in the container that holds the cap or closure. It must be compatible with the cap or closure and can be broadly classified by size (i.e., diameter) and sealing method (e.g., twist cap, cork, etc.). Although glass is an excellent barrier to water vapor, gases, and odors, an incorrectly designed or applied closure may negate the benefits that glass packaging offers in protecting foods from deterioration.

Metals

Four metals are commonly used for the packaging of foods: steel, aluminum, tin, and chromium. Tin and steel, and chromium and steel, are used as composite materials in the form of tinplate and electrolytically chromium-coated steel (ECCS), the latter being somewhat unhelpfully referred to as tin-free steel (TFS). Aluminum is used in the form of purified alloys containing small and carefully controlled amounts of magnesium and manganese.

The term tinplate refers to low-carbon (~0.02–0.3%) mild steel sheet varying in thickness from approximately 0.15–0.5 mm with a coating of tin between 2.8 and 17 gsm (g m^{-2}) (0.4–2.5 μm thick) on each surface of the material. Tinplate is manufactured by electrolytically applying a thin coating of tin to a steel sheet, which, depending on the final application, contains various levels of carbon, silicon, manganese, phosphorous, copper, and sulfur. After plating, the coating is passivated by electrolytic treatment in sodium dichromate to render the surface more stable and resistant, and then lightly oiled. The final structure of the completed coating is shown in Figure 1.

The production of ECCS is very similar to electrotinning. ECCS consists of a duplex coating of metallic chromium and chromium sesquioxide to give a total coating weight of approximately 0.15 gsm, much thinner than the lowest grade of electrolytic tinplate. The surface of ECCS is more acceptable for protective enamel/lacquer coatings, printing inks, and varnishes than tinplate. However, ECCS is less resistant to corrosion than tinplate and therefore must be enameled on both sides.

Aluminum, the earth's most abundant metallic constituent, is used to manufacture both metal cans and thin foil in thicknesses ranging from 4 to 150 μm; foils thinner than 20 μm contain minute pinholes that are permeable to gases and water vapor. In both applications, alloying agents including silicon, iron, copper, manganese, magnesium, chromium, zinc, and titanium are added to impart strength, and improve formability and corrosion resistance.

Paper

Pulp is the fibrous raw material used for the production of paper, paperboard, corrugated board, and similar manufactured products. It is obtained from plant fiber and is therefore a renewable resource. The cell wall of softwoods, which are preferred for most pulp products, typically contain 40–44% cellulose, 25–29% hemicelluloses, and 25–31% lignin by weight. Compared to hardwoods, softwoods have fibers that are generally up to 2.5 times longer. As a result, hardwoods produce a finer, smoother, but less strong sheet.

Pulping refers to the reduction of wood or other fibrous raw materials to a fibrous mass, the purpose being to separate the fibers without damaging them so that they can then be reformed into a paper sheet in the paper-making process. The intercellular substances (primarily lignin) must be softened or dissolved to free individual fibers. Commercial pulping is accomplished by either mechanical, thermal, chemical, or a combination of these treatments. Pulps that retain most of the wood lignin deteriorate in color and strength quite rapidly; most or all of the lignin can be removed by cooking wood with solutions of various chemicals and the pulps thus produced are known as chemical pulps. In contrast, mechanical pulps are produced by pressing logs onto a grindstone when the heat generated by friction softens the lignin so that the fibers separate with very little damage. Mechanical pulps can also be formed by grinding wood chips between two rotating refiner plates. In addition, there are some processes that are categorized as semichemical and chemimechanical. The most prevalent process is chemical pulping, which accounts for

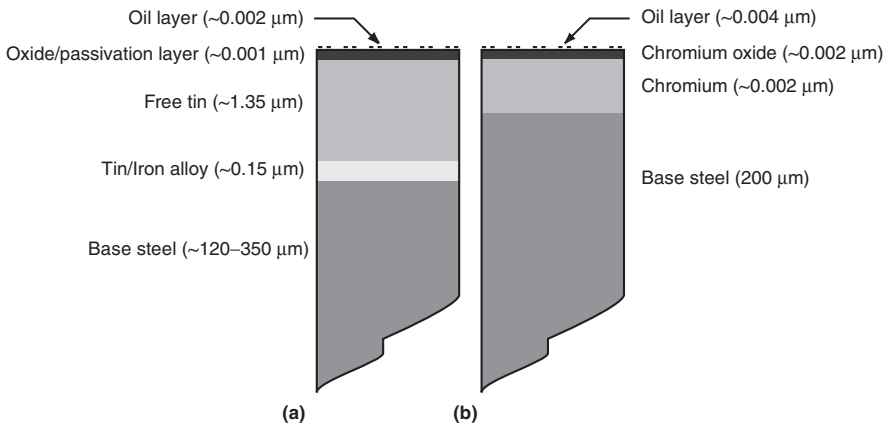

Figure 1 Schematic structure (not to scale) of (a) tinplate and (b) ECCS showing the main functional layers. Reproduced with permission from Robertson, G.L., 2013. Food Packaging: Principles & Practice, third ed. Boca Raton, FL: CRC Press.

>70% of the worldwide production of pulp, of which kraft pulping is the most prevalent at 80%.

Almost all paper is converted after manufacture by undergoing further treatment such as embossing, coating, laminating, and forming into special shapes and sizes such as bags and boxes. Further surface treatment involving the application of adhesives and printing inks are common, depending on the end use.

Paper and paperboard (>250 gsm) are poor barriers to gases and water vapor; uncoated paper packaging provides little more than protection from light and minor mechanical damage. For example, a sized commercial kraft linerboard of 200 gsm has a water vapor transmission rate (WVTR) at 50% RH/ 23 °C of 426 g m^{-2} day^{-1}. In many packaging applications, a barrier is needed against water vapor and/or gases such as O_2. A water barrier can be formed by changing the wettability of the paper surface with sizing agents, whereas coating the paper with plastic polymers provides a good barrier to gases and water vapor. Beverage cartons consist of layers of paperboard coated internally and externally with low-density polyethylene (LDPE), resulting in a carton that is impermeable to liquids and in which the internal and external surfaces may be heat sealed. There may also be a thin layer (6.5 μm) of aluminum foil, which acts as a gas and light barrier.

Plastics

Plastics are organic polymers with the unique characteristic that each molecule is either a long chain or a network of repeating units. The properties of plastics are determined by the chemical and physical nature of the polymers used in their manufacture, the properties of polymers being determined by their molecular structure, molecular weight (MW), degree of crystallinity, and chemical composition (Ebnesajjad, 2013). These factors in turn affect the density of the polymers and the temperatures at which they undergo physical transitions.

Polymer chains can and do align themselves in ordered structures, and the thermodynamics of this ordered state determine such properties as melting point T_m, glass transition temperature T_g, and mechanical and electrical properties. However, it is the chemical nature of the polymer that determines its stability to temperature, light, water, and solvents, and hence the degree of protection it will provide to food when used as a packaging material. A wide range of polymers is used in food packaging and the major categories are briefly reviewed in Section Polyolefins.

Polyolefins

These form an important class of thermoplastics and include low-, linear-, and high-density polyethylenes (LDPE, LLDPE, and HDPE) and polypropylene (PP). The polyethylenes have the nominal formula $-(CH_2-CH_2)_n-$ and are produced with a variable amount of branching, each branch containing a terminal methyl ($-CH_3$) group. Branch chains prevent close packing of the main polymer chains.

LDPE is a tough, flexible, slightly translucent material that provides a good barrier to water vapor but a poor barrier to gases. It is widely used to package foods and is easily heat sealed to itself. LLDPE contains numerous short side chains and has improved chemical and puncture resistance and higher strength than LDPE. HDPE has a much more linear structure than LDPE, is stiffer and harder, and provides superior oil and grease resistance. It is used in both film form where it has a gray, translucent appearance, and as rigid packs such as bottles. PP is a linear polymer with lower density, higher softening point, and better barrier properties than the polyethylenes. In film form it is commonly used in the biaxially oriented state (BOPP) where it has sparkling clarity; it can also be blow- and injection-molded to produce closures and thin-walled containers.

Copolymers of ethylene

For copolymers of ethylene, the other comonomer can be an alkene such as propene, butene, hexene, or octene, or a compound having a polar functional group such as vinyl acetate (VA), acrylic acid (AA), ethyl acetate (EA), methyl acrylate (MA), or vinyl alcohol (VOH). The two most important ethylene copolymers in food packaging are discussed below.

Ethylene-vinyl acetate (EVA) is a random copolymer of ethylene and VA whose properties depend on the VA content and MW. For example, EVA with a VA content of 3–12% is similar in flexibility to plasticized PVC. As the VA content increases, EVA becomes more elastic and less crystalline, resulting in an increase in permeability to gases, water vapor, fats, and oils. EVA has three advantages over LDPE: a lower heat-sealing temperature, better barrier properties, and excellent stretch properties. Thus, it finds use as a cling-wrap and stretch film for food packaging (particularly fresh meat) and has replaced PVC for many stretch-wrapping applications.

Ethylene-vinyl alcohol (EVOH) copolymers are produced by a controlled hydrolysis of EVA copolymer, the hydrolytic process transforming the VA group into VOH; there is no VOH involved in the copolymerization. EVOH copolymers offer not only excellent processability, but also superior barriers to gases, odors, aromas, etc. when dry. It is these characteristics that have allowed plastic containers incorporating EVOH barrier layers to replace many glass and metal containers for packaging food. Generally, as the ethylene content increases, the gas barrier properties decrease and the water vapor barrier properties improve.

Substituted olefins

Monomers in which each ethylene group has a single substituent are called vinyl compounds and the properties of the resultant polymers depend on the nature of the substituent, MW, crystallinity, and degree of orientation. Disubstituted monomers with two substituents on the one carbon are called vinylidene.

Polyvinyl chloride (PVC) has a repeating unit of $(-(CH_2-CHCl)_n-)$ and a range of PVC films with widely varying properties can be obtained from the basic polymer. The two main variables are changes in formulation (principally plasticizer content) and orientation.

Thin, plasticized PVC film was widely used for the stretch-wrapping of trays containing fresh red meat and produce, with the relatively high WVTR of PVC preventing condensation on the inside of the film. Oriented films are used for shrink-wrapping of produce and fresh meat, but in recent years

LLDPE films have increasingly replaced them in many applications.

Unplasticized PVC as a rigid sheet material is thermoformed to produce a wide range of inserts from chocolate boxes to biscuit trays. Unplasticized PVC bottles have better clarity, oil resistance, and barrier properties than those made from HDPE but are softened by certain solvents, notably ketones and chlorinated hydrocarbons. They are used for a wide range of foods including fruit juices and edible oils, but in recent years PVC has been increasingly replaced by PET.

Polyvinylidene chloride (PVdC) has a repeating unit of $(-(CH_2-CCl_2)_n-)$ and the homopolymer yields a rather stiff film, which is unsuitable for packaging purposes. When PVdC is copolymerized with 5–50% (but typically 20%) of vinyl chloride (VC), a soft, tough, and relatively impermeable film results. Although the films are copolymers of VdC and VC, they are usually referred to simply as PVdC copolymer and their specific properties vary according to the degree of polymerization and the properties and relative proportions of the copolymers present. Properties include a unique combination of low permeability to water vapor, gases, and odors, as well as greases and alcohols. They also have the ability to withstand hot filling and retorting and so find use as a component in multilayer barrier containers. As an important component of many laminates, PVdC copolymers can be sealed to themselves and to other materials. The copolymer is frequently used as a shrink film because orientation improves tensile strength, flexibility, clarity, transparency, and impact strength. As well, gas and water vapor permeabilities are lowered and tear initiation becomes difficult.

Polystyrene (PS) has the general formula $(-(CH_2-CHC_6H_5)_n-)$. Crystal grade PS can be made into film but it is brittle unless the film is biaxially oriented. Although a reasonably good barrier to gases, it is a poor barrier to water vapor. The oriented film can be thermoformed into a variety of shapes. To overcome the brittleness of PS, synthetic rubbers (typically 1,3-butadiene isomer $CH_2=CH-CH-CH_2$) can be added during polymerization at levels generally not exceeding 25% w/w for rigid plastics. The chemical properties of this toughened or high-impact polystyrene (HIPS) are much the same as those for unmodified or general purpose polystyrene (GPPS). HIPS is an excellent material for thermoforming and is also injection-molded into tubs, which find wide use in food packaging. Extruded PS foam sheet has high tensile strength, good water resistance, low water vapor transmission, ease of fabrication, excellent thermal insulating capability, low weight, and good cushioning characteristics. This combination of properties leads to a wide spectrum of applications in food packaging.

Polyesters

Polyethylene terephthalate (PET) is a condensation polymer produced by the esterification of ethylene glycol (EG) with terephthalic acid (TPA) or dimethyl terephthalate (DMT) and has the general formula $(-OOC-C_6H_5-COOCH_2-CH_2-)_n$. In contrast to the carbon-carbon links in the polymers discussed previously, polyesters are based on carbon–oxygen–carbon links where one of the carbons is part of a carbonyl group. The outstanding properties of PET film as a food packaging material are its great tensile strength, excellent chemical resistance, light weight, elasticity, and stability over a wide range of temperatures (−60° to 220 °C). PET films are most widely used in the biaxially oriented, heat-stabilized form.

To improve the barrier properties of PET, coatings of LDPE and PVdC copolymer have been used. PET film extrusion-coated with LDPE is very easy to seal and very tough. Two-side PVdC copolymer-coated grades provide a high barrier, and a major application is the single-slice cheese wrap. PET is also used to make 'ovenable' trays for frozen foods and prepared meals, where they are preferable to foil trays because of their ability to be microwaved without the necessity for an outer paperboard carton.

PET bottles are stretch-blow molded, the stretching or biaxial orientation being necessary to get maximum tensile strength and gas barrier, which in turn enables bottle weights to be low enough to be economical.

Polyamides

Polyamides (PAs) are condensation, generally linear thermoplastics made from monomers with amine and carboxylic acid functional groups resulting in amide (–CONH–) linkages in the main polymer chain that provide mechanical strength and barrier properties. Nylon 6 refers to PA made from a polymer of ε-caprolactam; one material is used that has 6 carbon atoms. Nylon 11 refers to PA made from a polymer of ω-undecanolactam, which has 11 carbon atoms. Films from nylon 6 have higher temperature, grease, and oil resistance than nylon 11 films.

Nylon 6,6 is formed by reacting hexamethylenediamine with adipic acid. Both materials each contain 6 carbon atoms. Nylon 6,10 is made by reacting hexamethylenediamine with sebacic acid $(HOOC-(CH_2)_8-COOH)$. The diamine has 6 carbon atoms and is numerically first, followed by the acid that contains 10 carbon atoms.

A relatively new polyamide is MXD6 made from *meta*-xylylene diamine and adipic acid, the 6 indicating the number of carbon atoms in the acid. It has better gas barrier properties than nylon 6 and PET at all humidities, and is better than EVOH at 100% RH, due to the existence of the benzene ring in the MXD6 polymer chain. Biaxially oriented film produced from MXD6 is used in several packaging applications as it has significantly higher gas and water vapor barrier properties, and greater strength and stiffness, than other PAs. Together with its high clarity and good processability, the above properties make MXD6 film suitable as a base substrate for laminated film structures for use in lidding and pouches, especially when the film is exposed to retort conditions.

Biobased plastics

Starch

Starch is the most common annually renewable raw material and is mainly extracted from cereals and tubers. Native starch is not a true thermoplastic but can be converted into a plastic-like material called thermoplastic starch (TPS). In the presence of plasticizers at high temperature (90–180 °C) and under shear, starch readily melts and flows, allowing for its use as an extrusion, injection-molding or blow-molding material, similar to most conventional petroleum-based thermoplastic polymers. Although TPS can be processed in the same way as traditional plastics, its sensitivity to water vapor and poor

mechanical properties make it unsuitable for many applications. TPS properties reach equilibrium only after several weeks.

Commercial water-resistant, starch-based bioplastics are produced by using blends of biodegradable petroleum-derived polymers and starch. These materials are made with gelatinized starch (60–85%) and hydrophilic (e.g., EVOH) or hydrophobic petroleum-derived biodegradable polymers (e.g., polycaprolactone) and compatibility agents. The polyesters form the continuous phase leading to materials having relative water resistance and acceptable barrier and mechanical properties.

Chitosan

Chitin is, after cellulose, one of the most abundant polysaccharides produced in nature and is particularly abundant in the exoskeleton of arthropods and the cell walls of insect cuticles. Chitosan is a hydrophilic polysaccharide derived from chitin by deacetylation with alkalis. Although both chitin and chitosan can be extruded to make films for food packaging applications, their main use is as an edible coating to extend the shelf life of fresh fruits and vegetables. Films made only from chitosan lack water resistance and have poor mechanical properties. Both chitin and chitosan have antimicrobial activity, which can be a useful attribute in many food packaging applications to improve quality and extend shelf life.

Polylactic acid

Polylactic acid (PLA) is a linear, aliphatic polyester synthesized from lactic acid monomers. The ester linkages in the polymer are sensitive to both enzymic and chemical hydrolysis. Lactic acid can be produced cheaply by the fermentation of glucose obtained from the starch in biomass such as corn or wheat, or from lactose in whey, or sucrose in molasses. The properties of PLA are similar to LDPE but its rigidity is much higher due to a higher T_g (58 °C compared to −25 °C for LDPE).

PLA biodegrades at temperatures above the T_g and therefore can only be composted in industrial composters where high temperatures are generated. Degradation of PLA is primarily due to hydrolysis of the ester linkages, which occurs more or less randomly along the backbone of the polymer. Two major challenges to the stabilization of PLA with regard to hydrolysis are that it is quite permeable to water and the hydrolysis reaction is autocatalytic.

Poly(hydroxyalkanoates)

Poly(hydroxyalkanoates) (PHAs) are linear aliphatic polyesters consisting of homo- or co-polymers of β-hydroxyalkanoic acids that can be produced from the fermentation of sugars by, for example, *Cupriavidus necator*. They are produced in the form of intracellular particles that accumulate as a carbon and energy sink when certain microorganisms are grown under nutrient stress in the presence of excess carbon. Poly(hydroxybutyrate) (PHB) is the most common polymer but by manipulating the growth medium, a random copolymer containing both 3-hydroxybutyrate (HB) and 3-hydroxyvalerate (HV) is obtained: poly(hydroxybutyrate *co*-hydroxyvalerate) or PHBV. By changing the ratio of HV to HB, the resulting copolymer can be made to resemble either PP (low HV) or LDPE (high HV) with regard to flexibility, tensile strength, and melting point. PHB/V has good chemical and moisture resistance as well as good O_2 and aroma barrier properties.

Biopolyethylene

Bioethylene is produced by the catalytic dehydration of bioethanol, which can be made by fermentation of various feedstocks including sugarcane, sugar beet, and wheat grain. Biopolyethylene (BioPE) has characteristics equivalent to those of conventional polyethylene and can be used in identical applications. From bioethylene it is possible to produce all the polyethylene types: HDPE, LDPE, and LLDPE.

Biopolyethylene terephthalate

It is now possible to make biopolyethylene terephthalate (bioPET) using EG derived from sugarcane, and TPA or DMT produced from biobased *para*-xylene (PX) by converting fermentation-derived isobutanol into PX using several traditional chemical processes such as dehydration, dimerization, and cyclization. Commercial production is expected by 2015. Of course, the bioPET has identical properties to petrochemical-based PET, i.e., it can be recycled but is not biodegradable.

Regenerated cellulose film

Regenerated cellulose film (RCF) (commonly referred to by the generic term cellophane, which is still a registered trade name in some countries) is manufactured from highly purified cellulose (usually derived from bleached sulfite wood pulp) and is therefore a biobased and renewable material. However, it is not a plastic as it will not melt and cannot be formed by heat and pressure; it can be regarded as transparent paper. For food packaging applications it is plasticized (typically with EG) and coated on one or both sides; the type of coating largely determines the barrier properties of the film. The most common coatings are LDPE, PVC, and PVdC copolymer; it can also be metallized with aluminum particles.

Packaging Material Properties

The ability to quantify the properties of packaging materials and the resulting packages is critical to the design and development of packaging that will serve its intended functions. It is necessary to be aware of just what properties are essential at the package development stage. Although the dangers of underperformance of food packaging are usually well understood, overperformance is equally to be avoided in light of the high costs of packaging materials and societal pressures to reduce the quantity of packaging materials used commercially.

Mechanical Properties of Metals, Glass, Paper, and Plastic Packaging

The mechanical properties of a packaging material, together with the effectiveness of the package closure or seal, determine the ability of a package to maintain integrity, i.e., its protective properties under physical stress. A number of tests are used to assess the packaging material strength under tension, compression, bursting, tearing, or impact forces.

Metals

Carbon is the most important alloying element for steel and affects the strength of cans, a higher carbon content usually being combined with a higher manganese content, resulting in higher strength steel. Lower carbon content improves material formability and weldability. To reduce the possibility of severe fluting, paneling, or creasing, and to impart the desired surface finish, steel is given a final, light cold rolling in a 'temper' mill. This imparts springiness to the steel but changes the temper or surface hardness only slightly. Temper refers to an arbitrary number designation that indicates the forming properties of tin and is the summation of interrelated mechanical properties such as elasticity, stiffness, springiness, and fluting tendency.

The combination of tin and steel produces a material that has good strength, combined with excellent fabrication qualities such as ductility (the capability to undergo extensive deformation without fracture) and drawability (these attributes arise from the grade of steel selected and the processing conditions employed in its manufacture), as well as good weldability, nontoxicity, lubricity, lacquerability, and a corrosion-resistant surface of bright appearance (these latter properties are due to the unique properties of tin). Furthermore, the tin coating adheres sufficiently to the steel base so that it withstands any degree of deformation that the steel is able to withstand without flaking.

Compared with tinplate and ECCS, aluminum is a lighter, weaker, but more ductile material that cannot be soldered. Aluminum has a higher strength to weight ratio but less tensile strength than steel. The high ductility allows aluminum to be shaped and formed with relative ease. Most commercial uses of aluminum require special properties that the pure metal cannot provide. Therefore, alloying agents are added to impart strength, improve formability characteristics, and influence corrosion characteristics. A wide range of aluminum alloys is commercially available for packaging applications, depending on the container design and fabrication method used.

Glass

Because of its amorphous structure, glass is brittle and usually breaks because of an applied tensile stress. It is now generally accepted that fracture of glass originates at small imperfections or flaws, the large majority of which are found at the surface. A bruise or contact with any hard body on the glass surface produces very small cracks or checks that may be invisible to the naked eye. However, because of their extreme narrowness, they cause a concentration of stress that may be many times greater than the nominal stress at the section containing them. Because glass cannot yield, the applied stress (when it is high enough) causes these flaws to propagate. Thus, it is the ultimate tensile strength of a glass surface that determines when a container will break. In practice, a stress concentrator may be a small crack or check induced in the manufacturing process, or a scratch resulting from careless container handling. Therefore, the major step taken to make glass more break-resistant involves the elimination of surface flaws (e.g., microcracks) by careful handling during and after forming and annealing, because the condition of the surface has a great deal to do with its tensile properties.

The mechanical strength of a glass container is a measure of its ability to resist breaking when forces or impacts are applied. Glass deforms elastically until it breaks in direct proportion to the applied stress. Although the mechanical strength of a glass bottle or jar can increase with glass weight, this is at the expense of thermal strength, which decreases with increasing glass weight.

Paper

The strength and mechanical properties of paper depend on the mechanical treatment of the fibers and the inclusion of fillers and binding materials. Paper has a definite grain caused by the greater orientation of fibers in the direction of travel of the paper machine, and the greater strength orientation that results partly from the greater fiber alignment and partly from the greater tension exerted on the paper in this direction during drying. The grain direction is known as the machine direction (MD), whereas the cross direction (CD) is the direction of the paper at right angles to the MD. Most of the physical properties of paper depend on direction, i.e., the MD, CD, and thickness direction (z direction), and these must be taken into account in measuring all physical properties and clearly indicated when reporting test results.

Papers vary in MD:CD strength ratios, and usually there is less variation in paper properties in the MD than in the CD because variations occur slowly in the MD, whereas in the CD they may occur quite suddenly for a variety of process-related reasons. In addition, the CD strength normally varies depending on how far the sample was taken from the edge of the sheet. In general, papers should be used to take greatest advantage of the grain of the paper.

Plastics

The four properties tensile and yield strength, elongation and Young's modulus are usually considered together because the same equipment is used for measuring each of them. It is usual when carrying out tensile tests to plot the stress against the strain, i.e., the load against the elongation. A great deal of information about the material can be obtained from the shape of its stress/strain curve. In addition to the numerical values for tensile strength, Young's modulus, elongation, and so on, it is possible to obtain some idea of the toughness of the material by measuring the area under the curve. Some mechanical properties of plastics are given in Table 1. One problem that arises when considering the strength of thermoplastic polymers is the time and temperature dependence of the changes that occur under mechanical stress.

Optical Properties of Glass and Plastic Packaging

Glass, because it has no crystalline structure, is optically isotropic when it is homogeneous and free from any stresses. The optical properties of glass relate to the degree of penetration of light and the subsequent effect of that transmission, transmission being a function of wavelength. The spectral transmission of glass is determined by reflection at the glass surface and the optical absorption within the glass. In silicate glasses, transmission is limited by the absorption of silica at approximately 150 nm in the UV and at 6000 nm in the IR region. Iron impurities further reduce transmission in the UV and near-IR regions.

Table 1 Mechanical properties of some biobased and petroleum-derived polymers

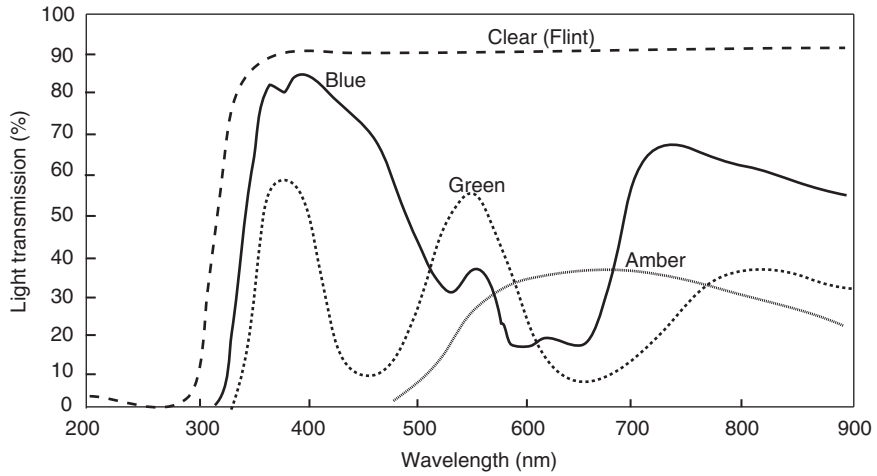

Figure 2 Typical light transmission properties of common container glasses. Reproduced with permission from Robertson, G.L., 2013. Food Packaging: Principles & Practice, third ed. Boca Raton, FL: CRC Press.

Light transmission may be controlled by the addition of coloring additives such as metallic oxides, sulfides, or selenides. Most of the transition metal oxides (e.g., cobalt, nickel, chromium, iron, etc.) give rise to absorption bands, not only in the visible but also in the UV and IR regions of the spectrum. The three main colors of glass used to produce food containers are flint or clear, amber or brown, and green, and the typical light transmission of these glasses is shown in Figure 2.

A light-resistant container is defined as one that passes no more than 10% of incident radiation at any wavelength between 290 nm and 450 nm through the average sidewall thickness. Amber glass provides this degree of light protection quite economically, as shown in Figure 2.

Optical properties of plastics are related to both the degree of crystallinity and the actual polymer structure. Optical properties of importance with thermoplastic polymers include clarity, haze, color, transmittance, reflectance, gloss, and refractive index. The clarity of a film indicates the degree of distortion of an object when viewed through the film, with 'see-through' clarity referring to the ability of the film to resolve fine details of fairly distant images viewed through the film.

Barrier Properties of Plastic Packaging

Unlike metal and glass packages, plastic packages are permeable and the concept of permeability is normally associated with the quantitative evaluation of the barrier properties of a plastic. A plastic that is a good barrier has a low permeability. This section is concerned with aspects of the solution,

diffusion and permeation of gases and vapors ('permeants') in effectively nonporous polymeric materials.

The protection of foods from gas and vapor exchange with the environment depends on the integrity of packages (including their seals and closures), and on the permeability of the packaging materials themselves. The barrier properties of plastics indicate their resistance to sorption and diffusion of substances such as gases and flavor and aroma compounds.

Under steady-state conditions, a gas or vapor diffuses through a polymer at a constant rate if a constant pressure difference is maintained across the polymer. The diffusive flux, J, of a permeant in a polymer can be defined as the amount passing through a plane (surface) of unit area normal to the direction of flow during unit time as follows:

$$J = Q/At \quad [1]$$

where Q is the total amount of permeant that has passed through area A during time t.

The relationship between the rate of permeation and the concentration gradient is one of direct proportionality and is embodied in Fick's first law:

$$J = -D\frac{\delta c}{\delta x} \quad [2]$$

where J is the flux (or rate of transport) per unit area of permeant through the polymer, c is the concentration of the permeant, D is the diffusion coefficient, and $\delta c/\delta x$ is the concentration gradient of the permeant across thickness δx. D reflects the speed at which the permeant diffuses through the polymer and is a function of temperature and may also be of concentration. Equation [2] can be used to calculate the steady-state rate of diffusion assuming that D is constant and the concentration is a function only of the geometric position inside the polymer.

Consider a polymer X mm thick, of area A, exposed to a permeant at pressure p_1 on one side and at a lower pressure p_2 on the other as shown in Figure 3. The concentration of permeant in the first layer of the polymer is c_1 and in the last layer c_2.

When steady-state diffusion has been reached, J=constant and eqn [2] can be integrated across the total thickness of the polymer X, and between the two concentrations, assuming D to be constant and independent of c:

$$JX = -D(c_2 - c_1) \quad [3]$$

and

$$J = \frac{D(c_2 - c_1)}{X} \quad [4]$$

By substituting for J using eqn [1], the quantity of permeant Q diffusing through a polymer of area A in time t can be calculated:

$$Q = \frac{D(c_2 - c_1)At}{X} \quad [5]$$

Rather than the actual concentration, it is more convenient when the permeant is a gas to measure the vapor pressure p, which is at equilibrium with the polymer, rather than measure the actual concentration. Henry's law applies at low

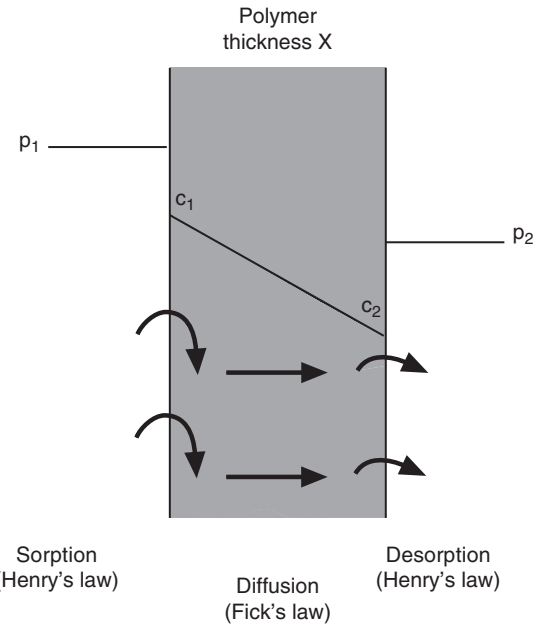

Figure 3 Permeability model for gas or vapor transfer through a polymer. Reproduced with permission from Robertson, G.L., 2013. Food Packaging: Principles & Practice, third ed. Boca Raton, FL: CRC Press.

concentrations and c can be expressed as:

$$c = Sp \quad [6]$$

where S is the solubility coefficient of the permeant in the polymer (it reflects the amount of permeant in the polymer). By combining eqns [5 and 6],

$$Q = \frac{DS(p_1 - p_2)At}{X} \quad [7]$$

The product DS is referred to as the permeability coefficient or constant and is represented by the symbol P:

$$P = DS \quad [8]$$

Thus, the permeability coefficient is the product of a kinetic term (D), which reflects the dynamics of the penetrant-polymer system, and of a thermodynamic term (S), which depends on the penetrant-polymer interactions. P represents the ease with which a gas permeates through a polymer when subjected to a pressure gradient.

$$P = \frac{QX}{At(p_1 - p_2)} \quad [9]$$

or

$$\frac{Q}{t} = \frac{P}{X}A(\Delta p) \quad [10]$$

The term P/X is called the permeance; it is not a property of the material but a performance evaluation indicator.

Although steady-state is usually attained in a few hours for small molecules such as O_2, larger molecules in barrier polymers (especially glassy polymers) can take a long time to reach steady-state, with this time possibly exceeding the anticipated

Table 2 Broadly representative permeability coefficients of various polymers and permeants at 25 °C and 0% RH unless indicated otherwise in barrer (10^{-10} cm^3 (STP) cm cm^{-2} s^{-1} (cm Hg)$^{-1}$)

shelf life. Although D and S are independent of concentration for many gases such as O_2, N_2, and, to a certain extent, CO_2, this is not the case where considerable interaction between polymer and permeant takes place (e.g., water and hydrophilic films such as EVOH and PAs, or many solvent vapors diffusing through polymer films).

Although the chemical structure of a polymer can be considered to be the predominant factor that controls the magnitude of P, it also varies with the morphology of the polymer and depends on many physical factors such as density, crystallinity, and orientation.

Consideration of eqn [9] suggests that the dimensions of P are:

$$P = \frac{(\text{quantity of permeant under stated conditions})(\text{thickness})}{(\text{area})(\text{time})(\text{pressure drop across polymer})} \quad [11]$$

The quantity of permeant can be expressed in mass, mole, or volume units. For gases, volume is preferred, expressed as the amount permeating under conditions of standard temperature and pressure (STP: 273.15 K and 1.013 25×10^5 Pa). Although more than 30 different units for P appear in the scientific, commercial, and patent literature, the American Society for Testing and Materials (ASTM) has adopted a single unit for P called the *barrer* (B) after the New Zealander Richard Maling Barrer (1910–1996), a pioneer in gas transport through membranes. It is defined as 10^{-10} cm^3 (STP) cm cm^{-2} s^{-1} (cm Hg)$^{-1}$. The SI units of kg m m^{-2} s^{-1} Pa^{-1} are found occasionally in the scientific literature where the exponential term is 10^{-18}. Broadly representative permeability coefficients for a number of polymers to several gases and water vapor are presented in Table 2.

The above treatment of steady-state diffusion assumed that both D and S are independent of concentration but in practice deviations do occur. Equation [9] does not hold for heterogeneous materials such as coated or laminated films, or when there is interaction between polymer and permeant. The property is then defined as the transmission rate (TR) of the material, where:

$$\text{TR} = \frac{Q}{At} \quad [12]$$

where Q is the amount of permeant passing through the polymer, A is the area, and t is the time. Permeabilities of polymers to water and organic compounds are often presented in this way, and in the case of water and O_2, the terms WVTR and oxygen transmission rate (OTR) are in common usage.

It is critical that the thickness of the film or laminate, the temperature and the partial pressure difference of the gas or water vapor are specified for a particular TR.

Typically, units of (g m^{-2} day^{-1}) are used for WVTR and (ml m^{-2} day^{-1}) for OTR. Often the WVTRs are given for so-called tropical conditions of 38 °C/90% RH but sometimes for so-called temperate conditions of 25 °C/75% RH; OTRs are often given for 23 °C/0% RH. Such data for a variety of polymer films of 25 μm (2.5×10^{-3} cm) thickness are given in Table 3.

TR is related to P as follows:

$$P = \frac{QX}{At\Delta p} = \text{TR}\frac{X}{\Delta p} \quad [13]$$

Factors Affecting Permeability

Both compositional and environmental factors affect permeability. Compositional factors include permeant size and shape, polymer morphology, polymer additives, and permeant-polymer interactions. A major environmental factor is temperature, which influences both the solubility and diffusion coefficients as follows:

$$P = DS = D_o S_o \exp\{-(E_d + \Delta H_s)/RT\} = P_o \exp(-E_p/RT) \quad [14]$$

where ΔH_s is the heat of sorption of the permeant in the polymer, E_d is the activation energy for the diffusion process, and E_p is the apparent activation energy for permeation. For all known permeant-polymer pairs, P increases with temperature.

Many foods require more protection than a single material can provide to give the product its intended shelf life. Where increased barriers to gases and/or water vapor are necessary, it is more economical to incorporate a thin layer of barrier material than to simply increase the thickness of a monolayer. Provided that the permeability coefficients of the individual layers are independent of the permeant partial pressure, the permeability coefficient of the multilayer film, P_T, can be calculated using the equation:

$$P_T/X_T = (P_1/X_1) + (P_2/X_2) + \ldots\ldots(P_n/X_n) \qquad [15]$$

where X_T is the total thickness of the multilayer film, and the permeability coefficients and thickness of the individual layers are designated by 1,2,……,*n*.

Food Packaging and Shelf Life

The quality of most foods and beverages decreases with storage or holding time, from which it follows that there will be a finite length of time before the product becomes unacceptable. This time from production to unacceptability is referred to as shelf life and includes the time in warehouses and the distribution chain, as well as time on the retailer's shelf and in the consumer's home. The shelf life of a food is controlled by:

- formulation and processing parameters (intrinsic factors);
- the environment the product is exposed to during distribution and storage (extrinsic factors);
- the properties of the package.

Examples of intrinsic factors include pH, water activity a_w, enzymes, microorganisms, and concentration of reactive compounds. Many of these factors can be controlled by selection of raw materials and ingredients, as well as the choice of processing parameters. Examples of extrinsic factors include temperature, relative humidity, light, total pressure, and partial pressure of different gases, and mechanical stresses including consumer handling. Many of these factors can affect the rates of deteriorative reactions that occur during the shelf life of a product (Robertson, 2010).

The properties of the package can have a significant effect on many of the extrinsic factors and thus indirectly on the rates of the deteriorative reactions. In summary, the shelf life of a food can be altered by changing its composition and formulation, processing parameters, packaging system, or the environment to which it is exposed.

Moisture-Sensitive Foods

When a food is placed in an environment at a constant temperature and relative humidity, it eventually comes to equilibrium with that environment. The corresponding moisture content at steady-state is referred to as the equilibrium moisture content (m_e). When a range of moisture contents (expressed as mass of water per unit mass of dry matter) is plotted against its corresponding relative humidity or a_w at constant temperature, a moisture sorption isotherm (MSI) results. Such plots are very useful in assessing the stability of moisture-sensitive foods and selecting effective packaging.

The expression for the steady-state permeation of a gas or vapor through a thermoplastic material was derived previously (see eqn [9]) and can be rewritten as:

$$\frac{\delta w}{\delta t} = \frac{P}{X} A(p_1 - p_2) \qquad [16]$$

where $\delta w/\delta t$ represent the rate of gas or vapor transport across the film, the latter term corresponding to Q/t in the integrated form of the expression (eqn [9]).

The prediction of moisture transfer either to or from a packaged food requires analysis of the above equation given certain boundary conditions. If it is assumed that P/X is constant, that the external environment is at constant temperature and humidity, and that p_2, the vapor pressure of the water in the food, follows some simple function of the moisture content, then a simple analysis can be made.

However, because external conditions do not remain constant during storage, distribution, and retailing of a packaged food, P/X is not constant. If the food is being sold in markets in temperate climates, then WVTRs determined at 25 °C/75% RH can be used. A 'worst-case' analysis can be made using WVTRs determined at 38 °C/90% RH. A further assumption is that the moisture gradient inside the package is negligible, i.e., the package should be the major resistance to water vapor transport, which is the case for most films under high humidity conditions.

Consideration of eqn [16] indicates that the internal vapor pressure is not constant but varies with the moisture content of the food at any time. Consequently, the rate of gain or loss of moisture is not constant but falls as Δp gets smaller. Thus to be able to make accurate predictions, some function of p_2, the internal vapor pressure, as a function of the moisture content must be inserted into the equation. Assuming a constant rate results in the product being overprotected.

In low and intermediate moisture foods, the internal vapor pressure is determined solely by the MSI of the food. In the simplest case when the isotherm is treated as a linear function:

$$m = b\,a_w + c \qquad [17]$$

where m, moisture content in g H_2O per g solids; a_w, water activity; b, slope of isotherm; c, constant.

The moisture content can be substituted for water gain and after some mathematical manipulation the following expression is obtained:

$$\ln\frac{m_e - m_i}{m_e - m} = \frac{PAp_o}{XW_s b}t \qquad [18]$$

where m_e, equilibrium moisture content of the food if exposed to external package RH; m_i, initial moisture content of the food; m, moisture content of the food at time t; p_o, vapor pressure of pure water at the storage temperature (not the actual vapor pressure outside the package); W_s, weight of dry solids inside the package.

The end of product shelf life is reached when $m = m_c$, the critical moisture content, at which time $t = \theta_s$, the shelf life.

Equations such as eqn [18] have been extensively tested for foods and found to give excellent predictions of actual weight gain or loss (Robertson, 2011). These equations can be used to calculate the effect on shelf life of changes in the permeability of the packaging film, external conditions such as temperature and humidity, the surface area:volume ratio of the package, and variations in the initial moisture content of the product.

Oxygen-Sensitive Foods

Oxygen is the gas of major importance in packaged foods because it plays a crucial role in many reactions that affect shelf life (e.g., microbial growth, color changes in fresh and cured meats, oxidation of lipids and consequent rancidity, and senescence of fruits and vegetables). The transfer of gases and odors through packaging materials can be analyzed in an analogous manner to that described for water vapor transfer, provided that values are known for the permeance of the packaging material to the appropriate gas, and the partial pressure of the gas inside and outside the package.

The principal difference between predominantly water vapor-sensitive and O_2-sensitive foods is that the latter are generally more sensitive by two to four orders of magnitude. Thus, the amount of O_2 present in the air-filled headspace of O_2-sensitive foods must not be neglected when predicting their shelf life. A further complicating factor with O_2-sensitive foods is that a concentration gradient occurs much more frequently than in moisture-sensitive foods.

Assuming that resistances of headspace and food to O_2 diffusion are negligible, the unsteady-state material balance for oxygen content of the headspace is (Krochta, 2007):

$$\frac{\delta p_{O2}}{\delta t} = \frac{PA(p_{O1} - p_{O2})}{VX} - r_O W \qquad [19]$$

where p_{O1} is the O_2 partial pressure outside the package (constant at 0.21 atm), p_{O2} is the O_2 partial pressure inside the package, t is time since the packaging of the food, V is the package headspace volume, W is the weight of the food, r_O is the O_2 reaction rate per unit weight of food, and P, X, and A are as defined earlier. The simplest solution is obtained when r_O can be related to p_{O2} with a linear equation, permitting r_O to be integrated over time and the shelf life θ_s calculated when the quantity of O_2 (Q_O) permeating into the food has reached the limit of acceptability. An even simpler approach that does not require an equation relating r_O to p_{O2} is to assume that O_2 reacts immediately on entering the package, that p_{O2} is zero, and that steady-state is reached rapidly. Equation 19 can then be simplified to

$$\frac{PA(p_{O1})}{X} = r_O W \qquad [20]$$

Given that

$$r_O = Q_O/\theta_s \qquad [21]$$

Then

$$\theta_s = \frac{Q_O WX}{PAp_{O1}} \qquad [22]$$

This approach gives a conservative estimate of shelf life.

Packaging Systems

Modified Atmosphere Packaging

Modified atmosphere packaging (MAP) is being successfully used around the world to extend the shelf life and retain the quality of a wide variety of foods. MAP is the enclosure of food in a package in which the atmosphere inside the package is modified or altered to provide an optimum atmosphere for increasing shelf life while maintaining food quality. Modification of the atmosphere may be achieved either actively or passively. Active modification involves displacing the air with

a controlled, desired mixture of gases, and is generally referred to as gas flushing. Passive modification (also known as commodity-generated MA) occurs as a consequence of the food's respiration and/or the metabolism of microorganisms associated with the food; the package structure normally incorporates a polymeric film and so the permeation of gases through the film (which varies depending on the nature of the film and the storage temperature) also influences the composition of the atmosphere that develops.

In vacuum packaging, elevated levels of CO_2 can be produced by microorganisms or by respiring fruits and vegetables. Thus vacuum packaging of respiring foods or foods containing viable microorganisms such as flesh foods is a form of MAP because after initial modification of the atmosphere by removal of most of the air, biological action continues to alter or modify the atmosphere inside the package.

With the exception of baked goods, MAP is always used in association with chill temperatures (usually taken as $-1°$ to $+7$ °C). The preservative effect of chilling can be greatly enhanced when it is combined with modification of the gas atmosphere because many deteriorative reactions involve aerobic respiration in which the food or microorganism consumes O_2 and produces CO_2 and water. By reducing O_2 concentration, aerobic respiration can be slowed. By increasing CO_2 concentration, microbial growth can be slowed or inhibited.

The normal composition of air by volume is 78.08% nitrogen, 20.95% oxygen, 0.93% argon, 0.03% carbon dioxide, and traces of nine other gases in very low concentrations. The three main gases used in MAP are O_2, CO_2, and N_2, either singly or in combination. Although the literature on their application and benefits is limited, noble or 'inert' gases such as argon are being used commercially for a wide range of products. Argon is 1.43 times denser than N_2 and can thus be made to flow like a liquid through air spaces whereas N_2 cannot. Use of carbon monoxide (CO) and sulfur dioxide (SO_2) has also been reported for specific foods.

The gas mixtures used for MAP of different foods depend on the nature of the food and the likely spoilage mechanisms. Where spoilage is mainly microbial, the CO_2 levels in the gas mix should be as high as possible, limited only by the negative effects of CO_2 (e.g., package collapse when CO_2 is absorbed by the food) on the specific food. Typical gas compositions for this situation are 30–60% CO_2 and 40–70% N_2. For O_2-sensitive products where spoilage is mainly by oxidative rancidity, 100% N_2 or N_2/CO_2 mixtures (if microbial spoilage is also important) are used. For respiring products it is important to prevent anaerobic respiration by avoiding too high a CO_2 level or too low an O_2 level.

The recommended concentrations of O_2 and CO_2 for fruits and vegetables can be found in the published literature, and a very effective way of plotting this data with CO_2 concentration as the ordinate and O_2 concentration as the abscissa is presented in **Figure 4** for fruits (Kader *et al.*, 1998). The windows represent the boundary of recommended gas concentrations; the smaller the window the more rigid the design requirement.

The permselectivity β of plastic films is defined as the ratio of the permeability coefficients of CO_2:O_2. For air β is approximately 0.8; this is represented by the line A–D in **Figure 4**. An otherwise impermeable package with a few small holes can be used to create atmospheres along this line that passes through the window for berry fruits and figs. Line A–B is plotted for a β of 5.0, which is approximately the value for LDPE and PVdC copolymer films. This line bisects several windows indicating that these films could be used successfully for some fruits. However, PVdC copolymer is suitable only for produce with very low respiration rates because it has such low gas permeabilities (*see* **Table 2**). The CO_2–O_2 atmospheres that lie between the lines A–B and A–D may be created by using packages made from LDPE film with microperforations or microporous windows. However, the permselectivity ratios are not constant for a given polymer but increase as the temperature is lowered. For example, β for LDPE has been reported to range from 5.08 at 0 °C to 3.45 at 20 °C, and β for PVC from 6.0 at 5 °C to 4.0 at 40 °C. Line A–C is plotted for a β of 3.0.

Equipment for MAP must generally be capable of removing air from the package and replacing it with a mixture of gases. Three types of packaging equipment are generally used for MAP: chamber machines using preformed pouches or trays; snorkel machines using preformed bags or pouches; and horizontal or vertical form-fill-seal (FFS) machines using pouches or trays.

The main characteristics to be considered when selecting packaging materials for MAP are the package permeability to gases and water vapor, mechanical properties, heat sealability, and transparency. For nonrespiring products, all the common high gas barrier structures have been used in MAP, including laminates and coextruded films containing PVdC copolymer, EVOH, and PAs as a barrier layer. To provide a good heat seal and water vapor barrier, the inside layer is usually LDPE.

The choice of suitable packaging materials for the MAP of respiring produce such as fruits and vegetables is much more complex and no easy solutions are available due to the dynamic nature of the product. Ideally the packaging material should maintain a low O_2 concentration (3–5%) in the headspace and prevent CO_2 levels from exceeding 10–20%. As discussed earlier, few plastic polymers are able to do this. One solution to this problem is the use of microperforated films where the number and diameter of the perforations is related to the food being packed.

Aseptic Packaging

Aseptic packaging is the filling of sterile containers with a commercially sterile product under aseptic conditions, and then sealing the containers so that reinfection is prevented; that is, so that they are hermetically sealed. The term aseptic implies the absence or exclusion of any unwanted microorganisms from the food, container, or other specific areas, whereas the term hermetic (strictly air-tight) is used to indicate suitable mechanical properties to exclude the entrance of microorganisms into a package and gas or water vapor into (or from) the package. The term commercially sterile is generally taken to mean the absence of microorganisms capable of reproducing in the food under nonrefrigerated conditions of storage and distribution, thus implying that the absolute absence of all microorganisms need not be achieved.

The three major reasons for the use of aseptic packaging are (1) to take advantage of high temperature-short time (HTST)

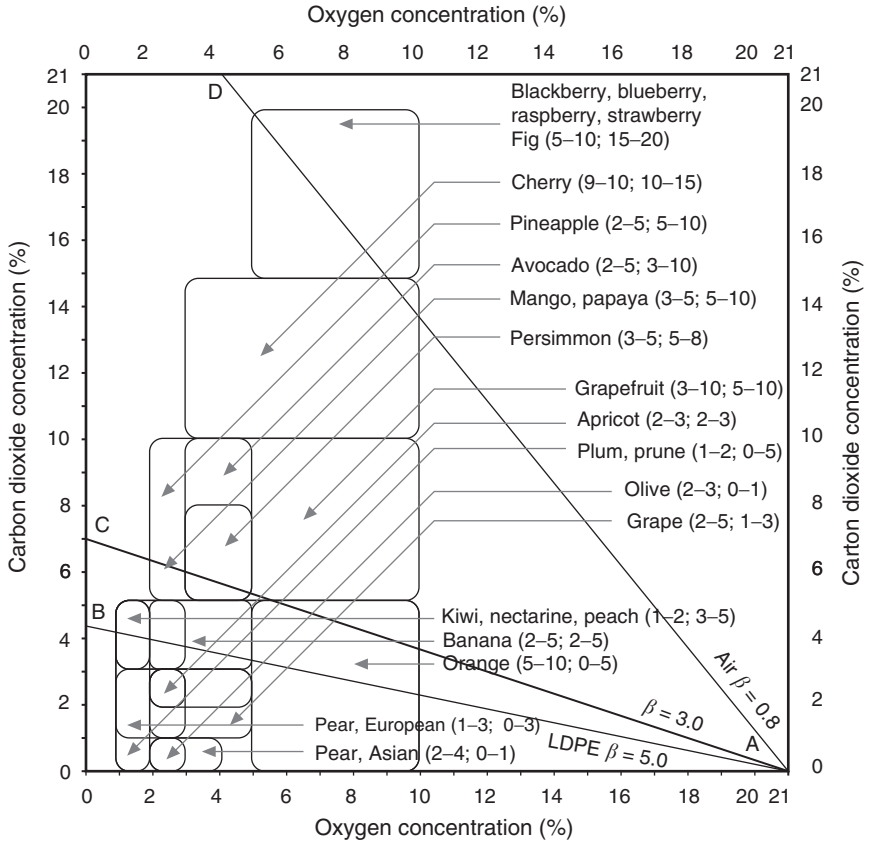

Figure 4 Recommended modified atmospheres for storage of fruits. Reproduced with permission from Kader, A.A., Singh, R.P., Mannapperuma, J.D., 1998. Technologies to extend the refrigerated shelf life of fresh fruits. In: Taub, I.A., Singh, R.P. (Eds.), Food Storage Stability. Boca Raton, FL: CRC Press, pp. 419–434.

sterilization processes, which are thermally efficient and generally give rise to products of a superior quality compared to those processed at lower temperatures for longer times, (2) to enable containers to be used that are unsuitable for in-package sterilization, and (3) to extend the shelf life of products at normal temperatures by packaging them aseptically.

Three main sterilization processes for packaging material are in common use, either individually or in combination: irradiation, heat, and chemical treatments. Irradiation involves ionizing radiation using gamma rays from cobalt-60 or cesium-137. The use of intense and short-duration pulses of broad-spectrum 'white' light (200–1000 nm) that generate high power levels can also sterilize aseptic packaging material and has recently been commercialized. UV radiation is most effective in terms of microbial destruction between 248 and 280 nm (the so-called UV-C range), with an optimum effectiveness at 253.7 nm. However, UV-C irradiation is generally only used commercially in combination with hydrogen peroxide (H_2O_2) as discussed below.

Heat sterilization processes can involve either steam (moist heat) or dry heat. For example, saturated steam at 165 °C and 600 kPa for up to 2 s is used to sterilize plastic containers. Hot air at a temperature of 315 °C has been used to sterilize paperboard laminate cartons where a surface temperature of 145 °C for 180 s is reached. A mixture of hot air and steam has been used to sterilize the inner surfaces of cups and lids made from PP, which is thermally stable up to 160 °C.

The lethal effect of H_2O_2 on microorganisms (including resistant spores) has been known for many years and is widely used to sterilize food packaging materials. When UV irradiation and H_2O_2 are used together they act synergistically, and the overall lethal effect is greater than the sum of the individual effects of peroxide and irradiation; the optimum effect is at a relatively low peroxide concentration of between 0.5% and 5%. Peracetic acid (PAA) is a liquid sterilant, which is particularly effective against spores. It is used for sterilizing filling machine surfaces as well as packaging materials such as PET bottles before aseptic filling, with the PET bottles being rinsed with sterile water rather than hot air.

The most widely used package is the paperboard laminate carton; it consists of layers of unbleached and/or bleached paperboard coated internally and externally with polyethylene, resulting in a carton that is impermeable to liquids and in which the internal and external surfaces may be heat sealed. There is also a thin (6.3 μm) layer of aluminum foil that acts as an O_2 and light barrier. The structure of a typical paperboard carton is shown in **Figure 5**.

Metal cans and glass bottles are used to a very limited extent for aseptic packaging. Blow-molded plastic bottles have been used for many years as a cheaper alternative to glass for nonreturnable containers. HDPE and PP were the two most

common thermoplastics used, sometimes with pigments added so that the contents are better protected from light. In recent years the use of PET has increased dramatically. Sachet and pouch systems are increasingly common, a typical material being a laminate of LLDPE with a center layer of EVOH copolymer and carbon black to give the pouch the required shelf life. Aseptic bag-in-box systems ranging in size from 1.5 to 1400 L are used for packaging UHT products. The bags contain EVOH and metallized PET as barrier layers and are manufactured fully sealed with minimum air content and then sterilized using gamma radiation. Preformed plastic cups are usually made from HIPS, PP or coextruded, multilayered polymers such as an outer layer of HIPS, a laminating adhesive, a barrier layer of PVdC or EVOH copolymer, a laminating adhesive, and finally LDPE. FFS cups are also available.

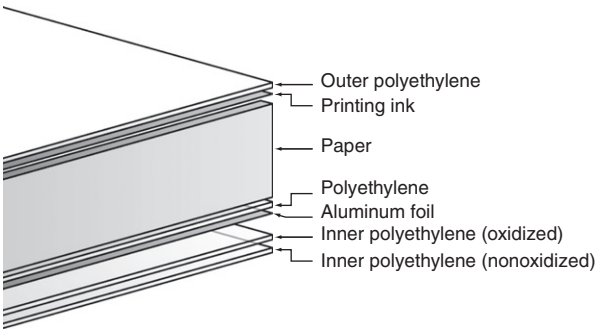

Figure 5 Typical structure of a paperboard laminate carton for aseptic filling. Reproduced with permission from Robertson, G.L., 2013. Food Packaging: Principles & Practice, third ed. Boca Raton, FL: CRC Press.

Assessment of package integrity is one of the most critical issues in the aseptic packaging of foods, and it is imperative that package integrity be maintained to ensure the safety and quality of the product. There is increasing interest in nondestructive (or noninvasive) package integrity testing, which allows the on-line testing of every package produced, while leaving both product and package intact. However, the availability of commercially viable, nondestructive package integrity testing equipment is still very limited.

Active Packaging

Active packaging is packaging in which subsidiary constituents have been deliberately included in or on either the packaging material or the package headspace to enhance the performance of the package system (Robertson, 2013). The two key words are deliberately and enhance. Implicit in this definition is that performance of the package system includes maintaining the sensory, safety, and quality aspects of the food. Selected examples of active packaging systems are given in Table 4.

A common type of active packaging involves the absorption or scavenging of O_2 inside the package. The most widely used O_2 scavengers consist of small sachets containing various iron-based powders together with an assortment of catalysts that scavenge O_2 within the food package and irreversibly convert it to a stable oxide. Water is essential for O_2 absorbents to function and in some sachets the water required is added during manufacture, whereas in others moisture must be absorbed from the food before O_2 can be absorbed. The iron powder is separated from the food by keeping it in a small sachet (labeled *Do not eat*) that is highly permeable to O_2 and,

Table 4 Selected examples of active packaging systems

Active packaging system	*Mechanisms*	*Food applications*
Oxygen absorbers	Iron-based, metal/acid, metal (e.g., platinum) catalyst, ascorbate/metallic salts, enzyme-based, nylon MXD6	Bread, cakes, cooked rice, biscuits, pizza, pasta, cheese, cured meats and fish, coffee, snack foods, dried foods, and beverages
Carbon dioxide absorbers/emitters	Iron oxide/calcium hydroxide, ferrous carbonate/metal halide, calcium oxide/activated charcoal, ascorbate/sodium bicarbonate	Coffee, fresh meats and fish, nuts and other snack foods, and sponge cakes
Ethylene absorbers	Potassium permanganate, activated carbon, activated clays/zeolites	Fruits and vegetables
Antimicrobial packaging	Organic acids, silver zeolite, spice and herb extracts, BHA/BHT antioxidants, vitamin E antioxidant, chlorine dioxide, sulfur dioxide	Cereals, meats, fish, bread, cheese, snack foods, fruits, and vegetables
Ethanol emitters	Encapsulated ethanol	Pizza crusts, cakes, bread, biscuits, fish, and bakery products
Moisture absorbers	Poly(vinyl acetate) blanket, activated clays and minerals, silica gel	Fish, meats, poultry, snack foods, cereals, dried foods, sandwiches, fruits, and vegetables
Flavor/odor adsorbers	Cellulose triacetate, acetylated paper, citric acid, ferrous salt/ascorbate, activated carbon/clays/zeolites	Fruit juices, fried snack foods, fish, cereals, poultry, dairy products, and fruits
Self-heating and self-cooling	Quicklime/water, ammonium nitrate/water, calcium chloride/water	Ready meals, beverages
Changing gas permeability	Side chain crystallizable polymers	Fruits and vegetables

Source: Reproduced from Day, B.P.F., 2008. Active packaging of food. In: Kerry, J., Butler, P. (Eds.), Smart Packaging Technologies for Fast Moving Consumer Goods. New York: John Wiley & Sons, Ltd., pp. 1–18.

in some cases, to water vapor. The overall reaction proceeds as follows:

$$Fe + \tfrac{3}{4}O_2 + 1\tfrac{1}{2}H_2O \rightarrow Fe(OH)_3 \quad [23]$$

O_2 scavengers have been used for a range of foods including sliced, cooked, and cured meat and poultry products, coffee, pizzas, specialty bakery goods, dried food ingredients, cakes, breads, biscuits, croissants, fresh pastas, cured fish, tea, powdered milk, dried egg, spices, herbs, confectionery, and snack food.

Sachets that contain $Ca(OH)_2$ in addition to iron powder absorb CO_2 as well as O_2 (sachets that absorb only CO_2 are rare). They find a niche application inside packages of roasted or ground coffee as fresh roasted coffee releases considerable amounts of CO_2 (formed by the Maillard reaction during roasting) that can cause swelling or even bursting of the package unless removed.

Attempts have been made to incorporate O_2-scavenging systems in a container lid or closure, with ascorbates or isoascorbates, either alone or in combination with sulfite, being the preferred O_2 scavengers. These compositions may be in a liquid or meltable form for application to a closure or as a component of a gasket. The scavenging properties of these compounds are activated by pasteurizing or sterilizing the container after sealing (de Abreu *et al.*, 2012).

During the ripening of fruits and vegetables the plant hormone ethylene (C_2H_4) is produced; it can have both positive and negative effects on fresh produce. Many C_2H_4-adsorbing substances have been described in the patent literature but those that have been commercialized are based on potassium permanganate, which oxidizes C_2H_4 in a series of reactions to acetaldehyde and then acetic acid, which can be further oxidized to CO_2 and H_2O, the overall reaction proceeding as follows:

$$3C_2H_4 + 12KMnO_4 \rightarrow 12MnO_2 + 12KOH + 6CO_2 \quad [24]$$

Other systems are based on the ability of certain materials to absorb ethylene, either alone or with an oxidizing agent such as finely divided and dispersed minerals, for example, zeolites, silicates, and activated carbon (de Abreu *et al.*, 2012).

Liquid water can accumulate in packages as a result of transpiration of horticultural produce, temperature fluctuations in high moisture packages, and drip or tissue exudate from flesh foods. This water can lead to the growth of molds and bacteria as well as fogging of films if allowed to build up in the package. Drip-absorbent pads consisting of granules of a superabsorbent polymer sandwiched between two layers of a microporous or nonwoven polymer have been used in the packaging of flesh foods to absorb liquid water. Polyacrylate salts, carboxymethyl cellulose, and graft copolymers of starch are the most frequently used polymers and they can absorb up to 500 times their own weight of liquid water.

Antimicrobial agents such as ethanol, silver ions, chlorine dioxide, sulfites, antibiotics, organic acids, enzymes, bacteriocins such as nisin, essential oils, and spices have been incorporated into packaging materials and used to prevent the growth of microorganisms on the food surface, leading to an extension in shelf life and/or improved microbial safety of the food. The burgeoning interest in antimicrobial food packaging is driven by increasing consumer demand for minimally processed, preservative-free foods. The use of antimicrobial films ensures that only low levels of preservative come into contact with the food compared to the direct addition of preservatives to the food.

Ethanol exhibits antimicrobial effects even at low concentrations and sachets containing ethanol (55%) and water (10%) adsorbed onto SiO_2 powder (35%) and filled into a paper/EVA copolymer sachet are available commercially. The sachet contents absorb moisture from the food and release ethanol vapor.

Despite considerable research over the past 20 years to develop and test films with antimicrobial properties to improve food safety and shelf life, few such systems are commercially available. Nisin is the antimicrobial most commonly incorporated into films, followed by acids and salts, chitosan, plant extracts, and the enzymes lysozyme and lactoperoxidase. A comprehensive quantitative analysis of the effectiveness of antimicrobial films for food applications revealed that the majority of results centered around 2 $\log_{10}$ reductions, suggesting that antimicrobial films still face limitations and are perhaps best viewed as part of a hurdle strategy to provide safe foods (Joerger, 2007). The legislative status of antimicrobials is also a limiting factor in their commercialization.

Intelligent Packaging

Intelligent is defined as 'having or showing understanding; clever, quick of mind' and the primary meaning intended when the word is applied to packaging is 'showing understanding.' Intelligent packaging is defined as packaging that contains an external or internal indicator to provide information about the history of the package and/or the quality of the food (Robertson, 2013). The key word in this definition is 'indicator' and includes indicators for gases, ripeness, and temperature including radio frequency identification (RFID) sensors but not RFID tags or labels because the latter do not indicate the history of the package or the quality of the food but merely its location. In summary, intelligent packaging senses some properties of the food it encloses or the environment in which the package is kept and is able to inform the manufacturer, retailer, or consumer about the state of these properties.

Quality or freshness indicators are used to indicate if the quality of the product has become unacceptable during storage, transport, retailing, and in consumers' homes. Intelligent indicators typically undergo a color change that remains permanent and is easy to read and interpret by consumers. Despite many attempts and several innovative approaches, no quality indicators are in widespread use by the food industry at present. Most have been based on detecting volatile metabolites such as diacetyl, amines, ammonia, and H_2S produced during the aging of foods. Others have responded to organic acids or volatile biogenic amines formed by microbial degradation of protein-containing foods such as putrescine from arginine, cadaverine from lysine, and histamine from histadine.

Time–temperature indicators (TTIs) are devices that integrate the exposure to temperature over time by accumulating

the effect of such exposures, and their response is usually expressed in a visually quantifiable identifier in the form of mechanical deformation, color development, or color movement (Taoukis, 2011). TTIs are based on irreversible physical, chemical, enzymic, or microbiological changes and the visible response reflects the cumulative time–temperature history of the package on which they are placed.

Many TTIs have been developed and the patent literature contains designs of more than 300 such devices. Maschietti (2010) reviewed the most relevant, recent patents based on the commercial success of the TTIs or their potential commercial viability, and the originality of the fundamental principles of the inventions. Although the majority of these devices were developed specifically for frozen foods, there is now widespread interest in TTIs for most categories of food, especially those where the rate of quality deterioration is highly temperature sensitive. An overview of the major types of TTIs, together with their application to food quality monitoring, has been presented by Taoukis (2011).

In developing an application of TTIs to shelf life monitoring, it is necessary to be able to define and measure quantitatively the key deteriorative reactions that contribute to quality loss in the particular food, and to integrate the expression for quality loss with the TTI response. Paramount to the success of any TTI is recognition of the fact that unless it has the same or similar E_A as the quality-determining deteriorative reaction in the food it is monitoring, it will overestimate or underestimate the loss of shelf life. The underlying requirement for the reliable prediction of food shelf life using a TTI is that the E_A of the TTI should be within ± 25 kJ mol^{-1} of the E_A of the key deteriorative reaction (Taoukis, 2011).

For many MAP applications (both gas flushing and vacuum packaging), it is helpful to know the gas concentration inside the package headspace and whether or not it is changing over time. Any changes can be as a result of enzymic activity in the food such as respiration of fruits and vegetables, deliberate absorption or generation of gas by added absorbers or generators as discussed in the Section Active Packaging, or loss of package integrity due to faulty seals or pinholes. The two gases of most interest are O_2 and, to a lesser extent, CO_2. Several types of gas indicators are available commercially, based on either colorimetric changes or luminescence. Many patents exist for colorimetric O_2 indicators and some have been commercialized, but they suffer from high costs and a lack of reliability due to their reversible nature (Mills *et al.*, 2012).

To date, most RFID tags have been used to increase convenience and efficiency in supply chain management and traceability, and are normally applied to secondary or tertiary packaging. To qualify as intelligent packaging, they must contain an indicator that provides information about aspects of the history of the package (e.g., its temperature) and the remaining shelf life or the quality of the food, and such intelligent RFID tags are now being commercialized. This provides for intelligent inventory management, and creates an opportunity to dramatically reduce the amount of expired product by first selling those products that the reader shows have the least shelf life left. An increasing number of systems are now available commercially. If costs can be reduced significantly, then they could find application on individual consumer packages although it is unclear what benefits they might provide to the consumer because a special reader is required to interpret them. However, such readers may be developed as applications for smart phones.

Recently, Potyrailo *et al.* (2012) demonstrated the applicability of passive (battery-free) RFID sensors for monitoring different aspects of food quality including freshness, aging, and spoilage. The electric field generated in the RFID sensor antenna extends from the plane of the RFID sensor and is affected by the ambient environment, thus providing the opportunity for sensing. This environment may be in the form of a food sample within the electric field of the sensing region or a sensing film deposited onto the sensor antenna.

To determine the milk spoilage rate, which is related to the changes in the dielectric properties of milk during storage, noninvasive determinations with RFID sensors were done directly through the walls of the original milk cartons. RFID sensors for monitoring fish freshness were constructed by draw-coating a polyaniline polymer to form a sensing film onto the antenna; such sensors had a detection limit of 500 parts per trillion (ppt) for ammonia gas. For monitoring bacterial growth, the RFID sensors measured the resonance impedance of the antenna circuit with the increase in response due to the accumulation of bacteria in the sensing region. To be accepted for diverse practical application scenarios, RFID sensors should have the ability for self-calibration and self-correction for variable ambient conditions such as temperature and repositioning.

Food Packaging and Sustainability

In its simplest sense, sustainable means to maintain or keep going continuously and it has been used in connection with forest management for more than a century. It is now accepted that sustainability has three dimensions or pillars: economic, environmental, and social. These three dimensions are also referred to as the triple bottom line or profits, planet, and people. Sustainable business practices integrate environmental concerns with social and economic ones. The metrics used for the measurement of sustainability are evolving and include indicators, benchmarks, standards, and certification systems.

There is no industry consensus as to what constitutes 'sustainable packaging' and the debate has been dominated by a narrow focus on reducing packaging weight and arguments around whether one material is more or less sustainable than another. However, the concept of sustainable packaging is more complex, and what may be the most sustainable solution for one product or particular market might not be the same elsewhere (Robertson, 2009).

The US-based Sustainable Packaging Coalition (SPC) defined sustainable packaging by listing eight criteria that relate to the activities of the packaging value chain and defined the areas in which they actively seek to encourage transformation, innovation, and optimization; the latest version is presented in **Table 5**. It is intended as a 'target vision' for companies to strive toward through continuous improvement and will evolve over time with new materials and technologies, leading to more sustainable packaging systems. The SPC claims quite correctly that their criteria blend broad sustainability objectives with business considerations and strategies that address

Table 5 Sustainable packaging criteria[a]

Is beneficial, safe, and healthy for individuals and communities throughout its life cycle
Meets market criteria for performance and cost
Is sourced, manufactured, transported and recycled using renewable energy
Optimizes the use of renewable or recycled source materials
Is manufactured using clean production technologies and best practices
Is made from materials healthy throughout the life cycle
Is physically designed to optimize materials and energy
Is effectively recovered and utilized in biological and/or industrial closed loop cycles

[a]No ranking is implied by the SPC in the order of criteria.

the environmental concerns related to the life cycle of packaging and the activities of the SPC membership. The SPC members believe that by successfully addressing these criteria, packaging can be transformed into a closed loop of packaging materials in a system that is economically robust and provides benefits throughout the life cycle – a sustainable packaging system.

The European Organization for Packaging and the Environment (Europen) believes it makes much more sense to talk about packaging and sustainability rather than sustainable packaging, which in the view of its members cannot be an end in itself. They recommend that packaging suppliers tell their customers how their packaging helps them to achieve their corporate sustainability goals. In the context of overall sustainability, packaging should (in their view) be regarded as part of the solution, not part of the problem, and as a net contributor to achieving the broad sustainability goal of resource optimization and waste minimization. In their view, packaging makes a valuable contribution to economic, environmental, and social sustainability through protecting products, preventing waste, enabling efficient business conduct, and providing consumers with the benefits of the products it contains.

Trying to reconcile 'sustainable packaging' and 'packaging and sustainability' is difficult if not impossible and is more than simply an exercise in semantics. How can the food industry expect the public to understand what it is doing to become more sustainable when the language and metrics are so confusing? Reaching a broad consensus on what may constitute sustainable packaging would provide the packaging industry with a platform from which to influence regulation as well as customer and consumer attitudes and expectations. One useful tool to compare different packages and assist in the development of more sustainable packaging is life cycle assessment (LCA).

Life Cycle Assessment

LCA is an environmental management tool that attempts to consider the resource and energy use, as well as the environmental impacts, over the entire life cycle of a package, product, or service from extraction of the raw materials through manufacture/conversion, distribution and use, to recovery or disposal. It is sometimes referred to as 'cradle to grave' analysis and typically compares two or more products that provide the same function or equivalent use. Thus an LCA makes it possible to isolate the stages in the life cycle of a process or product that make the most significant contribution to its environmental impacts. The ISO 14040 and 14044 international standards provide a framework for conducting LCAs.

Despite the increasing popularity of LCAs among both industry and governments, the technique does have significant limitations, which are often overlooked. One is that LCAs are not able to assess the actual environmental effects of emissions and wastes from the product or package because the actual effects depend on when, where, and how they are released into the environment.

Another is that LCAs take no account of economic factors such as the costs of raw materials, manufacturing, transport, and recovery or disposal. Furthermore, the conclusions from LCAs are specific only for the precise system under study and cannot be extrapolated to provide universal generalizations that, for example, one particular package is always better than another in every situation, or that reusable packaging is always better than single-use packaging.

Notwithstanding the limitations described above, LCA can be a very useful tool in two major areas. First, package design, development, and improvement all benefit from having LCA results available, which can help identify where significant resource use, wastes, and emissions occur, and thus suggest where significant changes or improvements can be made. Second, LCA can help decision-makers select the product or process that results in the least impacts to the environment. This information can be used with other factors, such as cost and performance data, to select a package or process. Third, LCA is a useful tool for assessing waste management options and planning integrated solid waste management systems on a case-by-case and regional basis.

In recent years, the carbon footprint (CFP) has been used to describe the greenhouse gas (GHG) emissions caused by a particular activity or entity, and thus a way for organizations and individuals to assess their contribution to global warming and climate change. Understanding these emissions, and where they come from, is necessary to reduce them. In this context, manufacturers are asking for the CFP associated with the manufacture, distribution, and disposal of products provided to them such as packaging. The CFP is expressed as CO_2 equivalents (abbreviated CO_2e).

Recently, Amienyo *et al.* (2013) presented the full life cycle impacts of carbonated soft drinks manufactured and consumed in the UK. Two functional units were considered: 1 l of packaged drink and total annual production of carbonated drinks. The system boundary was from 'cradle to grave' and the different packages considered were glass bottles (750 ml), aluminum cans (330 ml), and PET bottles (500 ml and 2 l). The study followed the ISO 14040/44 LCA methodology. Packaging was the main hotspot for most environmental impacts, contributing between 59% and 77%. The ingredients accounted for 7–14% (mainly due to sugar) and the manufacturing stage contributed 5–10%, largely due to the energy for filling and packaging. Refrigeration of the drink at retailers increased global warming potential (GWP) by up to 33%. Transport contributed up to 7% of the total impacts.

Table 6 Environmental profiles for the different life cycle stages of beverages

	Juice	*Beer*	*Water*
	1000 ml Aseptic carton	*330 ml Aluminum can*	*1500 ml PET bottle*
GWP[a] (g CO_2e)			
Beverage	29	713	6
Transport	35	36	34

Drinks packaged in 2 l PET bottles were the most sustainable option for most impacts, including the CFP, whereas drinks in glass bottles were the worst option. However, reusing glass bottles three times would make the CFP of the drink in glass bottles comparable to that in aluminum cans and 500 ml PET bottles. If recycling of PET bottles increased to 60% (currently 24%), the glass bottle would need to be reused 20 times to make their CFPs comparable. At the sectoral level, carbonated drinks in the UK are responsible for over 1.5 million tonnes of CO_2e emissions per year. This represented 13% of the GHG emissions from the whole food and drink sector or 0.26% of the UK total emissions in 2010.

Pasqualino *et al.* (2011) assessed the environmental impacts of the most common packaging options on the Spanish market for juice (aseptic cartons, glass, and HDPE bottles), beer (aluminum cans, glass, and HDPE bottles), and water (PET and glass bottles). The production of different packaging materials and sizes was evaluated, together with their method of final disposal (landfilling, incineration, and recycling). Recycling was found to be the most environmentally friendly disposal option for all the packaging alternatives compared, and either incineration or landfilling was considered the second best option depending on the packaging material. The packaging options with the lowest environmental impacts were aseptic cartons and plastic bottles (for sizes greater than 1 l). The environmental profiles of the whole beverage life cycles in terms of the GWP in g CO_2e and cumulative energy demand (CED) in megajoule (MJ) are summarized in **Table 6**. The impacts of beer packaging were similar to the impacts of beer production and these were the highest impact stages in the life cycle of beer. Packaging was found to have the highest environmental impacts in the life cycles of water and juice.

Glossary

Biofilms Multicellular communities (i.e., cell aggregates) that provide bacteria with the ability to grow adhered to biotic and abiotic surfaces.
Clones (or clonal groups) Genetically related (identical or similar) isolates of an organism derived from a single common ancestor.
Genotype The genetic information dictating a particular trait.
Phage type A set of bacterial strains susceptible to the same bacteriophages.
Phenotype Visible, expressed trait influenced both by the genetic information and the environment.
Quorum sensing Cell-to-cell communication in the context of which gene expression is regulated in response to changes in cell population density.
Serotype Group of isolates distinguished from others by the type of expressed surface antigens.
Shiga toxins Family of related toxins that inhibit protein synthesis, originally described to be produced by *Shigella dysenteriae*.
Strain An isolate (or group of isolates) that can be distinguished from other isolates of the same species by phenotypic or genotypic characteristics.
Zoonosis Any disease that can be transmitted from animals to humans.

Introduction

The appearance (or emergence) of new or unexpected pathogens in foods have been identified as one of the most important trends likely to affect food safety in the next 50 years (Tauxe *et al.*, 2010). Different, and often confusing, definitions have been proposed for 'emerging pathogens.' For instance, an emerging pathogen has been defined as a pathogen that is linked to a novel and serious to public health disease (Smith and Fratamico, 1995). In other cases, the term 'emerging' has been used to describe the appearance of microbial strains that have developed enhanced resistance to stresses and have adapted to new environments (Mor-Mur and Yuste, 2010). It has been proposed that, with particular reference to foodborne pathogens, the terms 'new,' 'evolving,' 'emerging,' and 'reemerging' should be differentiated and considered separately. In this sense, 'new foodborne pathogens' are serious hazards for public health and important causal agents of outbreaks that have not been previously described, whereas 'evolving foodborne pathogens' are those that become more potent (i.e., increased involvement in foodborne outbreaks) or more associated with other food products as well as those that were already known but not recognized as agents of human illness (Mor-Mur and Yuste, 2010). Finally, 'emerging foodborne pathogens' are foodborne pathogens that have newly arisen, meaning that they may have been recognized as pathogens but only recently are associated with foodborne transmission, whereas the 'reemerging' had been known for some time, but had fallen to low levels and are now showing increasing trends (Mor-Mur and Yuste, 2010; Sofos, 2008).

The emergence (or reemergence) of foodborne pathogens is a complex process and depends on the interaction of multiple factors including the following: (1) changes in agricultural practices (e.g., increased use of antibiotics in animal production); (2) microbial adaptation and evolution (e.g., enhanced virulence); (3) technological changes in the food industry (e.g., production, processing, packaging, and handling); (4) changes in human behavior and particularly in people's eating habits (e.g., increased consumption of raw/undercooked or minimally processed foods); (5) changes in demographics (e.g., migration, urbanization, aging of the population, and increasing number of people with conditions that result in immunosuppression); (6) health care and public health infrastructure; (7) environmental parameters (e.g., climate changes); (8) the global trade in foods leading to greater interdependence on the food safety systems of different countries; and (9) development of improved and more sensitive methodologies for the isolation, detection, and identification of foodborne pathogens (Miller *et al.*, 1998; Smith and Fratamico, 1995; Schofield, 1992; Tauxe *et al.*, 2010). In general, virtually any change affecting directly or indirectly the food chain is expected to create a selection pressure that will ultimately result in the emergence of foodborne pathogens (Miller *et al.*, 1998; Smith and Fratamico, 1995).

This article describes the characteristics, epidemiology, prevalence in foods, transmission routes to humans, and means of control of pathogens that are foodborne or have the potential to be foodborne, with a particular emphasis being placed on bacterial pathogens.

Bacteria

Aeromonas spp.

Aeromonas spp. are Gram-negative, rod-shaped, facultatively anaerobic, catalase-positive, chemoorganotrophic, nonspore-forming bacteria, and most of them are motile by polar flagella (Igbinosa *et al.*, 2012; Isonhood and Drake, 2002). This genus is characterized by considerable phenotypic variation, with gas

 doi:10.1016/B978-0-444-52512-3.00049-8

production being variable and often temperature dependent, whereas marked differences can also be observed in cellular morphology (Forsythe and Varnam, 2009). Aeromonads are easily differentiated from the bacterial species of the family Enterobacteriaceae, with which they share many biochemical characteristics, based on their positive oxidase reaction (Igbinosa *et al.*, 2012). The taxonomy and nomenclature of the genus *Aeromonas* have been complex and have undergone several changes over time (Igbinosa *et al.*, 2012; Janda and Abbott, 2010). Although formerly positioned in the family Vibrionaceae, the genus *Aeromonas* is now officially classified within the family Aeromonadaceae (Igbinosa *et al.*, 2012; Merino *et al.*, 1995). Furthermore, four *Aeromonas* species were originally identified: *Aeromonas hydrophila*, *Aeromonas sobria*, *Aeromonas caviae*, and *Aeromonas salmonicida*. However, distinct biochemical and genetic (i.e., deoxyribonucleic acid (DNA) hybridization) groups, referred to as phenospecies and genospecies, respectively, were later identified, resulting in significant reconsiderations on species designation and classification (Isonhood and Drake, 2002; Janda and Abbott, 2010). Currently, the genus comprises more than 15 species, with the latest research data indicating the existence of 13 phenospecies and 19 genospecies (Janda and Abbott, 2010).

Extensive variability in the optimum growth temperature of *Aeromonas* spp., with the latter growing optimally at temperature ranges between 22 and 35 °C (Igbinosa *et al.*, 2012; Isonhood and Drake, 2002). Indeed, optimum growth temperature has been one of the phenotypic markers (along with motility, production of indole, and elaboration of a melanin-like pigment on tyrosine agar) traditionally used for the differentiation of species of the genus into two major groups based on physiological properties and host specificity: (1) motile aeromonads, which grow optimally at 35–37 °C, are predicted to cause human infections and are represented by *Ae. hydrophila* and (2) nonmotile aeromonads, which grow optimally at 22–28 °C, are associated primarily with fish infections and are represented by *Ae. salmonicida* (Igbinosa *et al.*, 2012; Joseph and Carnahan, 2000). A few species can exhibit growth at a wide temperature range; for instance, *Ae. hydrophila* is capable of growing at temperatures ranging from 1 to 42 °C (Isonhood and Drake, 2002). The ability of many strains of the genus to grow at refrigeration temperatures (4–5 °C) has been well-established and long acknowledged as one of the most important factors contributing to the public health significance of aeromonads in foods (Buchanan and Palumbo, 1985; Kirov, 1993; Knøchel, 1990). Most *Aeromonas* spp. tolerate high pH well and can resist pH values ranging from 4.5 to 9.0, with the optimum pH being in the range 5.5–9.0 (Igbinosa *et al.*, 2012; Isonhood and Drake, 2002; Merino *et al.*, 1995). In general, aeromonads do not tolerate NaCl concentrations higher than 5% (Knøchel, 1990), whereas the lowest water activity (a_w) value allowing growth varies with the humectant (Merino *et al.*, 1995).

Aeromonas spp. are ubiquitous organisms, having the potential to be isolated from a wide range of environmental niches including aquatic habitats (surface water, groundwater, chlorinated, and nonchlorinated drinking water), natural soils, fish, foods, domesticated pets, invertebrate species, birds, and insects (Igbinosa *et al.*, 2012; Janda and Abbott, 2010). They are also found in raw sewage, sewage effluents, and sewage-contaminated waters and activated sludge (Dumontet *et al.*, 2001; Igbinosa *et al.*, 2012). Aeromonads have long been considered as opportunistic pathogens of both aquatic (warm- and cold-water fish) and terrestrial animals (Harikrishnan and Balasundaram, 2005; Isonhood and Drake, 2002; Queiroga *et al.*, 2012). Nonetheless, the motile mesophilic aeromonads, and particularly *Ae. hydrophila*, have been recently identified as emerging human pathogens, gaining continuously increasing public health recognition as potential causative agents of both gastrointestinal and extraintestinal infections, primarily in immunocompromized individuals (Cabral, 2010; Igbinosa *et al.*, 2012; Isonhood and Drake, 2002; Janda and Abbott, 2010; Merino *et al.*, 1995; Senderovich *et al.*, 2012).

Although not supported by the findings of volunteer human feeding studies, epidemiological data (i.e., presence of the organisms in the stools of individuals with diarrhea, in the absence of other known enteric pathogens) have frequently suggested aeromonads as putative enteropathogens (Forsythe and Varnam, 2009). Most human pathogenic strains are now recognized as being grouped into three genospecies: *Ae. hydrophila* hybridization group (HG) 1, *Ae. caviae* HG 4, and *Aeromonas veronii* biovar sobria HG 8 (Forsythe and Varnam, 2009). Gastroenteritis associated with aeromonads may vary in severity from mild, self-limiting diarrhea to dysentery or cholera-like illness with the latter being potentially life threatening (Forsythe and Varnam, 2009; Igbinosa *et al.*, 2012). Although *Aeromonas* spp. have been recognized as emerging human pathogens, their exact role as enteric pathogens has not been definitely established; their mechanisms of pathogenicity remain vague and their infectious dose is unknown (Forsythe and Varnam, 2009; Igbinosa *et al.*, 2012; Isonhood and Drake, 2002). Several putative virulence factors of *Aeromonas* spp. that can be associated with gastroenteritis have been identified including hemolysins, invasins, adhesins, endotoxin (or lipopolysaccharide), proteases, fimbriae, pili, capsular polysaccharides, S-layers, siderophores, and various extracellular enzymes (Igbinosa *et al.*, 2012; Isonhood and Drake, 2002; Merino *et al.*, 1995). Extraintestinal human infections associated with aeromonads include septicemia, meningitis, cellulitis, myonecrosis, peritonitis, hepatitis, pancreatic abscesses, respiratory, urogenital and eye infections, endocarditis, osteomyelitis, and septic arthritis (Forsythe and Varnam, 2009; Janda and Abbott, 2010; Roberts *et al.*, 2006; Talon *et al.*, 1998). At greatest risk for *Aeromonas* infections are people with predisposing conditions (e.g., deficient immune system, leukemia, and liver disease) as well as young (6 months to 2 years old) children (Forsythe and Varnam, 2009; Gracey, 1994).

The most common routes of infection suggested for *Aeromonas* spp. are the ingestion of contaminated water (drinking or natural mineral water) or food, and contact of the organisms with a break in the skin (e.g., when swimming in contaminated water) (Cabral, 2010; Igbinosa *et al.*, 2012). Despite the fact that the relative importance of water and food in *Aeromonas* infections has been the subject of considerable discussion, these two sources are most likely interrelated; given the strong association of aeromonads with water, it has been suggested that risk of human exposure is greatest through consumption of contaminated water, or food processed with contaminated water (Forsythe and Varnam, 2009). With particular reference to foods of animal origin, also significant in

the transmission of aeromonads to humans is expected to be the contribution of aeromonad-contaminated animals (symptomatic or not), with animal feces appearing to be the major source of contamination of foods (Igbinosa *et al.*, 2012). Furthermore, given their wide environmental distribution in conjunction with their ability to form biofilms, which may provide increased resistance to conventional bactericidal treatments, *Aeromonas* spp. may establish niches in food-processing equipment, with the latter potentially serving as a source of cross-contamination of foods in the absence of sufficient cleaning and sanitation (Cotton and Marshall, 1998; Isonhood and Drake, 2002).

Aeromonas spp. have been isolated from a wide range of foods of both plant and animal origin including fresh vegetables, fish, shellfish, meat, poultry, and dairy products (**Table 1**). Despite their frequent presence in foods, *Aeromonas* isolates may be nontoxigenic questioning their foodborne pathogen potential (Kirov, 1993). Indeed, *Aeromonas* spp. occur commonly on minimally processed produce items as well as on fresh fish, meat, and poultry as part of their normal spoilage microflora (Forsythe and Varnam, 2009; Jacxsens *et al.*, 1999; Samelis, 2006). Although potentially pathogenic, genospecies of *Aeromonas* have been occasionally isolated from food samples (Neyts *et al.*, 2000; Forsythe and Varnam, 2009), the link between food contamination and human disease can be definitely established only via confirmed epidemiological data. Nevertheless, such data are limited as only few foodborne outbreaks associated with *Aeromonas* spp. have been documented with the majority of them involving seafood (Altwegg *et al.*, 1991; Ghenghesh *et al.*, 2008; Isonhood and Drake, 2002; Kirov, 1993). A recent foodborne outbreak of *Ae. hydrophila* was reported in a college in China; more than 200 students were reported to be sick with acute diarrhea and, as supported by the findings of the conducted epidemiological investigation, the most probable source of the organism was salad ingredients washed in contaminated tank water (Qian *et al.*, 2012).

In continuation to its initial recognition as an agent of human illness, the genus *Aeromonas* is being considered as a pathogen of emerging importance due to a number of special features, including its ubiquitous presence in water and food, the abundance of virulence factors, and the psychrotrophic nature of many of its isolates (Smith and Fratamico, 1995; Vivekanandhan *et al.*, 2005). Another issue of major importance for the public health significance of *Aeromonas* spp. is the increasing documentation of isolates exhibiting resistance to several antimicrobial agents (Queiroga *et al.*, 2012). Hence, in the context of basic control procedures common for all foodborne pathogens (i.e., prevention of contamination, reduction of contamination, and prevention of microbial growth), the aforementioned issues need to be particularly addressed with regard to aeromonads. Water used for washing of food, and particularly of food products intended to be consumed raw such as fresh or minimally processed produce items, should be chlorinated or otherwise disinfected and care should be taken to ensure that water distribution systems are not colonized by *Aeromonas* spp. (Forsythe and Varnam, 2009). Although managing their growth in biofilms can be very difficult, the entry of aeromonads into water distribution systems can be significantly reduced through effective treatment and maintenance procedures, such as maintaining temperatures below 14 °C, providing free-chlorine levels above 0.1–0.2 mg l^{-1}, and limiting the levels of organic carbon compounds in the water (Igbinosa *et al.*, 2012). Regarding the control of the organisms in aquaculture systems, and, thus, in fish and seafood, proper disposal of diseased animals, maintaining high standards of water quality, temperature control, and disinfection of equipment are expected to be useful and effective approaches (Igbinosa *et al.*, 2012). Moreover, disease prevention by means of vaccination and immunostimulation of fish in aquaculture has been shown to be successful against several bacterial pathogens, including *Aeromonas* spp. However, alternative control approaches in aquaculture such as the application of probiotics and herbals may also be promising, while allowing at the same time for reduced cost of disease management compared with the use of antibiotics, chemicals, and vaccinations, as well as for reduced incidence of multidrug-resistant (MDR) *Aeromonas* strains (Harikrishnan and Balasundaram, 2005). Given that aeromonads are not particularly heat or acid resistant, they do not exhibit unusual resistance to conventional food-processing procedures (Isonhood and Drake, 2002), whereas nonthermal processing technologies such as irradiation are also expected to be effective against these organisms on various types of foods (Nagar and Bandekar, 2011). Therefore, as also supported by the findings of epidemiological investigations, particular emphasis needs to be placed on the prevention of contamination/recontamination of foods with the organisms via the implementation of appropriate sanitary measures such as proper food handling practices and efficient sewage disposal systems (Igbinosa *et al.*, 2012; Qian *et al.*, 2012). Furthermore, the implementation of improved diagnostic and detection procedures appears to be essential for proper surveillance of water, food, and sanitation facilities, as well as of human infections which may be considerably underestimated particularly in developing countries (Igbinosa, *et al.*, 2012; Qian *et al.*, 2012). The development of novel or the improvement of existing molecular-based techniques is expected to be very useful toward this direction, allowing for an enhanced detection of aeromonads and, thus, for clarification of their true role as pathogens (Ghatak *et al.*, 2012; Tichoniuk *et al.*, 2010). Finally, given that the pathogenesis of *Aeromonas* spp. is multifactorial, with a large number of virulence genes being identified and quorum-sensing signal molecules being potentially associated with the expression of virulence determinants, research on these fields of study will provide a better understanding of the mechanism(s) underlying the emergence of these organisms as human pathogens and help to develop effective diagnostics and novel therapeutics (Chan *et al.*, 2011; Yu *et al.*, 2005).

Arcobacter spp.

Arcobacter species are Gram-negative, spiral, curved to S-shaped, fastidious, and nonspore forming microorganisms belonging to the family Campylobacteraceae (Vandamme and De Ley, 1991). They are motile by a single unsheathed polar flagellum, exhibiting darting or corkscrew movement (Blackburn and McClure, 2009). The organisms were first isolated from aborted bovine and normal porcine fetuses, sows with

reproductive problems, and asymptomatic pigs (Ellis *et al.*, 1977, 1978; Neill *et al.*, 1978, 1979). The genus *Arcobacter* was proposed by Vandamme *et al.* (1991) to describe those organisms formerly designated 'aerotolerant campylobacters,' was classified along with the genera *Camplylobacter* and *Helicobacter* within the ribosomal ribonucleic acid (rRNA) Superfamily VI, and currently includes 12 recognized species: *Arcobacter butzleri*, *Arcobacter cryaerophilus*, *Arcobacter skirrowii*, *Arcobacter nitrofigilis*, *Arcobacter cibarus*, *Arcobacter halophilus*, *Arcobacter molluscorum*, *Arcobacter defluvii*, *Arcobacter marinus*, *Arcobacter trophiarum*, *Arcobacter mytili*, and *Arcobacter thereius* (Shah *et al.*, 2011). *Arcobacter* spp. can grow at temperatures ranging from 15 to 42 °C, at pH values between 5.5 and 9.5, and under both aerobic and anaerobic conditions with their optimal, however, growth occurring under microaerophilic conditions (i.e., 3–10% oxygen) (Blackburn and McClure, 2009; Vandamme *et al.*, 1991). The ability of arcobacters to grow at 15 °C under aerobic conditions is the basis for their differentiation from campylobacters with which they have similar morphological, metabolic, and several other phenotypic and genotypic features (Blackburn and McClure, 2009; Shah *et al.*, 2011).

Livestock animals, and primarily poultry and swine, constitute significant reservoirs of *Arcobacter* spp. (Phillips, 2001; Snelling *et al.*, 2006; Van Driessche *et al.*, 2004). Arcobacters have commonly been isolated from feces and rectal swabs of clinically healthy cattle, sheep, and horses at prevalences ranging from 3.6% to 41.7% (Shah *et al.*, 2011). According to the findings of De Smet *et al.* (2011), healthy small ruminants (i.e., primarily sheep and to a smaller extent goats) are important carriers of these organisms. In general, the presence of *Arcobacter* spp. in the feces of healthy livestock at slaughter poses an important risk of carcass, meat, and possibly milk (in the case of ruminants) contamination (De Smet *et al.*, 2011; Van Driessche *et al.*, 2003). Nevertheless, and despite their frequent isolation from poultry carcasses, organisms of the genus *Arcobacter* have rarely been isolated from the intestinal content of poultry, rendering the fecal origin of carcass contamination questionable and suggesting that contamination may occur at the postslaughter level (Houf and Van Driessche, 2007; Phillips, 2001; Van Driessche and Houf, 2007b; Van Driessche *et al.*, 2003). As demonstrated by the results of a study assessing the distribution of arcobacters in chickens, the organisms were isolated from neck skin samples but not from the intestinal tract or from the feathers; however, the way of sample collection and the time period for sample processing were identified as crucial parameters for the interpretation of such findings (Houf and Van Driessche, 2007). In addition to livestock, *Arcobacter* spp. have been isolated from wild and nondomesticated animals (e.g., raccoons, rhinoceroses, and gazelles) as well as from pets such as dogs and cats (Fera *et al.*, 2009; Houf *et al.*, 2008; Shah *et al.*, 2011). In spite of their natural occurrence in healthy animals, arcobacters have also been associated with animal infections, with their main clinical manifestations including abortion, mastitis, and enteritis (Phillips, 2001; Wesley, 1997). *Arcobacter* spp. have also been found in different water sources (e.g., sea, lake, river, canal, and groundwater), with the latter assumed to play a significant role in the transmission of the organisms to both animals and humans (Phillips, 2001; Snelling *et al.*, 2006; Shah *et al.*, 2011). More specifically, *Ar. butzleri* has been isolated from canal water, from well-water sources, as well as from water samples in water treatment plants from all stages of processing (Phillips, 2001). However, given the organism's sensitivity to chlorine, its presence in water is probably the result of either inadequate chlorination or posttreatment contamination (Phillips, 2001; Wesley, 1997). Furthermore, *Ar. butzleri* has been found in various types of sewage sludge (Phillips, 2001).

For a long time, the importance of *Arcobacter* spp. as human pathogens was uncertain, and still, very little is known about the epidemiology, pathogenesis, and real clinical significance of these organisms. The lack of a standard protocol for primary isolation and of routine screening procedures, as well as the similarity of the symptoms of *Arcobacter* infections with campylobacteriosis (i.e., *Campylobacter jejuni* infection) have hindered the assessment of infection rates (resulting in underestimation of infections) and the establishment of a definitive association between human illness and the pathogenicity of these organisms (Phillips, 2001; Shah *et al.*, 2011). On the basis of the findings of studies undertaken in Belgium and

France, *Ar. butzleri* was the fourth most common *Campylobacter*-like organism isolated from human stools, whereas *Arcobacter* presence has also been recorded in other countries such as Thailand and South Africa (Shah *et al.*, 2011). Indeed, predominantly *Ar. butzleri* and to a smaller extent *Ar. cryaerophilus* and *Ar. skirrowii* are the species with the strongest association with human disease (Shah *et al.*, 2011; Vanderberg *et al.*, 2004; Wesley, 1997). *Arcobacter* infections are mainly manifested in the form of enteritis with its main clinical symptoms being persistent and watery diarrhea with abdominal pain (at a higher frequency compared with campylobacteriosis), nausea, vomiting, and fever (Snelling *et al.*, 2006; Vanderberg *et al.*, 2004). In addition to its association with enteritis, it has been suggested that *Ar. butzleri* has the potential to invade other parts of the body and cause considerable complications. Indeed, the organism has been isolated from patients with liver cirrhosis and acute gangrenous appendicitis, from septicemic patients, as well as from the blood of uremic patients with hematogenous pneumonia (Shah *et al.*, 2011). Certain factors such as health status, age, and hypertension may predispose a person to *Arcobacter* infection (Shah *et al.*, 2011). The currently available knowledge regarding the dose response and pathogenicity of *Arcobacter* spp. is still very limited. Although some potential virulence factors have been identified, very little is known about the genes involved in the pathogenesis of these organisms (Houf and Stephan, 2007; Shah *et al.*, 2011; Snelling *et al.*, 2006). With regard to potential infection routes, these mainly include drinking of contaminated water (particularly in developing countries with inadequate water supplies), and consumption and handling of contaminated food (primarily raw or undercooked meat) (Ho *et al.*, 2006; Taylor *et al.*, 1991; Wesley, 1996, 1997). Nevertheless, contact with pets and person-to-person transmission have also been suggested as potential risk factors for human infections (Fera *et al.*, 2009; Houf *et al.*, 2008; Vandamme *et al.*, 1992).

Although the lack of a standard isolation method may result in considerable underestimation of their true occurrence in foods, *Arcobacter* spp. have been frequently isolated from products of animal origin with the highest prevalence being reported in poultry meat, followed by pork and beef (Blackburn and McClure, 2009; Cervenka, 2007; Shah *et al.*, 2011). The prevalence of the organisms in chicken can be as high as 100%, whereas the detection rates in beef, pork, mutton, and milk have been shown to range from approximately 1% to 50% (Cervenka, 2007; Shah *et al.*, 2011). However, arcobacters have not been found in eggs, and only rarely their incidence has been reported in seafood such as clams and mussels (Cervenka, 2007; Collado *et al.*, 2009). It was the isolation of arcobacters (and particularly *Ar. butzleri*, *Ar. cryaerophilus*, and *Ar. skirrowii*) over the last decade from various foods of animal origin that resulted in their classification as emerging foodborne pathogens by the International Commission on Microbiological Specifications for Foods (ICMSF, 2002), despite their very poor association with human foodborne diseases. Although an outbreak of recurrent abdominal cramps in a nursery and primary school in Italy in 1983 was associated with *Ar. butzleri*, with the successive timing of the cases suggesting a person-to-person transmission, no specific food vehicle was identified (Vandamme *et al.*, 1992). Only recently were arcobacters associated with an outbreak of foodborne illness; *Ar. butzleri* was identified as the most likely cause of a foodborne outbreak among attendees of a wedding reception in Wisconsin, US, with the collected epidemiological data demonstrating that rigorous investigation of outbreaks of undetermined etiology is valuable for enhancing one's understanding of emerging agents of foodborne diseases (Lappi *et al.*, 2013).

Arcobacters can easily be inactivated by heating food to an internal temperature of 70 °C as well as by chlorination (Shah *et al.*, 2011). Hence, the risk of transmission to humans of *Arcobacter* spp. via properly cooked foods and chlorinated water should be regarded as negligible (Wesley, 1996, 1997). With particular reference to poultry products, given that arcobacters are probably not normal inhabitants of the poultry intestine (Houf and Van Driessche, 2007; Phillips, 2001), control measures should be focused on preventing contamination of, and proliferation in, the broiler environment as well as at the postslaughter level (Blackburn and McClure, 2009). Although *Ar. butzleri* is believed to be more resistant to irradiation than *Ca. jejuni* (Phillips, 2001; Shah *et al.*, 2011; Wesley, 1997), irradiation with approximately 0.3 kGy for 10 s is sufficient for their inactivation (Shah *et al.*, 2011); thus, irradiation doses currently allowed for pork in the US (i.e., 0.3–1.0 kGy) should provide an effective means of reducing, if not completely eliminating, this organism from pork (Phillips, 2001). Furthermore, organic acid solutions, including those used widely in meat decontamination (e.g., acetic and citric acids at concentrations higher than 0.2%), have demonstrated considerable effectiveness and, therefore, application potential for controlling arcobacters on meat and poultry surfaces (Cervenka, 2007; Shah *et al.*, 2011; Skrivanova *et al.*, 2011; Snelling *et al.*, 2006). Being organisms of recent interest, there are no standard widely accepted methodologies for the detection, isolation, and typing of *Arcobacter* spp. (Blackburn and McClure, 2009). Although several methods using both aerobic and microaerophilic conditions and based on media for *Campylobacter* have been proposed, the currently available methods need to be improved in terms of specificity and sensitivity, with the development and application of molecular techniques gaining increasing interest (Blackburn and McClure, 2009; Douidah *et al.*, 2010; Shah *et al.*, 2011). Robust and reliable molecular typing methods along with basic research on the virulence characteristics of arcobacters are expected to contribute significantly to the accurate identification of this emerging foodborne pathogen as well as to a better understanding of its epidemiology and distribution both in the environment and in foods (Douidah *et al.*, 2010; Shah *et al.*, 2011; Snelling *et al.*, 2006). *Arcobacter* spp. exhibit susceptibility to aminoglycosides (e.g., kanamycin and streptomycin) and thus, the latter antibiotics may be regarded as suitable for the treatment of *Arcobacter* infections when adequate control of their use in veterinary and human medicine is in place (Snelling *et al.*, 2006). Nevertheless, due to the fact that there is evidence of acquired resistance of *Arcobacter* spp. to antimicrobials generally prescribed as first-line drugs for the treatment of campylobacteriosis (e.g., erythromycin, tetracycline, chloramphenicol, and ciprofloxacin), future research trends include studies on the number and diversity of antibiotic-resistant *Arcobacter* strains, as well as assessment of the transfer potential of antibiotic resistance genes among

Arcobacter spp. and between *Arcobacter* and *Campylobacter* (Blackburn and McClure, 2009; Snelling *et al.*, 2006).

Clostridium difficile

Clostridium difficile is a Gram-positive, spore forming, and anaerobic bacillus that has been relatively recently identified as a human pathogen (Dawson *et al.*, 2009; Gibbs, 2009). The first confirmed case of *Cl. difficile* infection (CDI) was reported in 1977 (Larson *et al.*, 1978), when the use of clindamycin was introduced and resulted in a rapid increase in the number of pseudomembranous colitis cases (Dawson *et al.*, 2009). *Cl. difficile* grows optimally at 35–40 °C, ferments amino acids in order to create adenosine triphosphate as an energy source, and can also utilize sugars (Gibbs, 2009). Extensive research on the genome of this bacterium has been carried out aiming at elucidating its mechanisms of infection and pathogenicity. Pathogenic strains of the organism produce two distinct toxins, both of which are high-molecular weight proteins capable of binding to specific receptors on the intestinal mucosal cells: (1) toxin A, an enterotoxin and (2) toxin B, a cytotoxin (Gibbs, 2009). Colonization of the gut by *Cl. difficile* and toxin production results in an acute inflammatory response and severe damage to the intestinal epithelium, particularly following treatment with broad-spectrum antibiotics (Dawson *et al.*, 2009; Rupnik, 2007). The organism, which may be naturally present in the gastrointestinal tract of healthy adults and infants, is usually kept under control by the normal intestinal microflora (Gibbs, 2009; Warren and Guerrant, 2011). When, however, certain antibiotics disrupt the protective gut microflora, indigenous or ingested spores of *Cl. difficile* germinate, multiply rapidly, colonize the gastrointestinal tract, and produce toxins (Dawson *et al.*, 2009; Gibbs, 2009; Warren and Guerrant, 2011). Although any broad-spectrum antibiotic can be associated with CDI, the latter has been primarily linked to clindamycin, cephalosporins, penicillins, and fluoroquinolones (Warren and Guerrant, 2011).

Since its initial recognition, the incidence and severity of CDI has considerably increased and *Cl. difficile* currently constitutes one of the most frequent causative agents of nosocomial diarrhea worldwide (Dawson *et al.*, 2009; O'Donoghue and Kyne, 2010; Rupnik, 2007). Symptoms of CDI may vary from mild diarrhea to life-threatening pseudomembranous colitis, and in addition to patients on antimicrobial treatment, the population at risk for the infection includes patients on other therapies that may also alter the balance of the gut microbiota (e.g., antacid/proton pump inhibitors and nonsteroidal antiinflammatory drugs), as well as the immunocompromized and the elderly (Dawson *et al.*, 2009). As a result of the worldwide increase in the incidence of CDI in the past decade, several molecular typing approaches have been developed in order to enhance the understanding of the epidemiology of *Cl. difficile*, including pulsed-field gel electrophoresis, restriction endonuclease analysis, toxinotyping (i.e., using sequencing data of toxins A and B), multilocus sequence typing, and polymerase chain reaction (PCR)-ribotyping (Dawson *et al.*, 2009). Recent changes in the epidemiology of *Cl. difficile* that have contributed to its characterization as a 'continually evolving pathogen' include (1) the emergence of new groups of highly virulent strains (e.g., strains with PCR-ribotype 027) causing outbreaks of increased disease severity, high relapse rate, and significant mortality in North America, Japan, and Europe (Dawson *et al.*, 2009; Gould and Limbago, 2010; Kuijper *et al.*, 2007; O'Donoghue and Kyne, 2010) and (2) the onset of community-acquired cases involving low-risk population groups (i.e., young individuals, not subjected to antibiotic therapy or previous hospitalization) (Gould and Limbago, 2010; Rupnik, 2007).

The increasing rate of community-associated cases of CDI has raised questions with regard to the routes of transmission of *Cl. difficile* to humans, with foodborne acquisition through consumption or handling of contaminated food products being hypothesized as a possible source of such infections (Gould and Limbago, 2010). In addition to constituting an important pathogenic organism for humans, *Cl. difficile* has also been recognized as an emerging animal pathogen (Rupnik, 2007; Songer and Anderson, 2006), and although a definitive link between the organism's carriage by animals and human disease has not been established, it has been suggested that food animals are likely to play an important role in the transmission of this pathogen to humans through food (Gould and Limbago, 2010). Indeed, there are several reports suggesting that food animals (both healthy and symptomatic) can be reservoirs for *Cl. difficile* (Dawson *et al.*, 2009; Simango and Mwakurudza, 2008; Thitaram *et al.*, 2011), whereas a marked overlap between isolates from animals and humans (including highly virulent outbreak subtypes) has also been documented (Keel *et al.*, 2007; Rupnik, 2007; Zidaric *et al.*, 2008). The organism can also be recovered from a wide variety of environmental sources including soil, seawater, and freshwater (Gould and Limbago, 2010). Hence, food products may become contaminated with *Cl. difficile* via multiple routes. With particular reference to meat and meat products, the organism could be either introduced during processing or be initially present in the muscle tissue (Rupnik, 2007). The presence of *Cl. difficile* spores in the feces of swine or beef cattle, for instance, may result in contamination of pork and beef products during slaughter (Thitaram *et al.*, 2011). In addition to meat and meat products, *Cl. difficile* has been isolated from a diverse set of foods such as chicken, produce, fish, and seafood (**Table 1**).

Given that broad-spectrum antibiotics exacerbate CDI, treatment of the disease is complicated with the administration of very few antibiotics, such as metronidazole and vancomycin, appearing to be effective (Kuijper *et al.*, 2007). As antibiotic resistance constitutes one of the most important virulence factors for *Cl. difficile*, attempts to prevent infections should focus on controlling the overall use of antibiotics, and particularly high-risk antibiotics such as cephalosporins, clindamycin, and fluoroquinolones (Dawson *et al.*, 2009; Kuijper *et al.*, 2007). However, it has been suggested that with the development of more potent antibiotics for other resistant bacterial pathogens, the problem of CDI is expected to continue (Warren and Guerrant, 2011). Therefore, despite the fact that new treatment options (both antibiotic and nonantibiotic alternatives) are becoming available (Kuijper *et al.*, 2007; O'Donoghue and Kyne, 2010), the antibiotic susceptibilities of *Cl. difficile* isolates need to be assessed and known; although such knowledge might not be relevant to the infection's treatment per se, it is expected to

facilitate the identification of the predisposing and prevailing antibiotic pressure to which this pathogen is subjected (Warren and Guerrant, 2011). In addition to classical virulence determinants such as toxin production and antibiotic resistance, the evaluation of other factors (e.g., increased gut colonization, increased resistance to bile salts, and increased motility/chemotaxis) should be very useful in explaining the emergence of epidemic *Cl. difficile* strains (Dawson *et al.*, 2009). Moreover, given that *Cl. difficile* spores can survive on surfaces for long periods of time and are resistant to many disinfectants, research on spore germination would provide useful information for controlling the spreading and persistence of this organism (Dawson *et al.*, 2009). With particular reference to community-associated cases of CDI, in order to understand the dynamics of and risk factors for the development of human disease, including the true occurrence and importance of foodborne transmission, more research covering the following areas is required (Gould and Limbago, 2010; Rodriguez-Palacios, *et al.*, 2010; Thitaram *et al.*, 2011): (1) determination of the infectious dose of *Cl. difficile*, which is currently unknown, and comparison of it with the microbial load typically present on contaminated foods at the time of consumption; (2) surveillance for human and animal infections utilizing standard subtyping systems capable of discerning common sources of these infections; (3) detailed strain typing and epidemiological investigations aiming at establishing the relationship between food animals and human isolates and, thus, determining the true potential for acquisition of foodborne disease; (4) development of consensus best practice methods for food testing; and (5) improving our understanding of the effects of heating (and assessment of the need for revising current cooking recommendations) and surface decontamination on *Cl. difficile* spores.

Cronobacter spp.

Cronobacter spp. are Gram-negative, facultatively anaerobic, and motile with peritrichous flagella rods, which are members of the family Enterobacteriaceae (Iversen *et al.*, 2008). The genus *Cronobacter*, formerly known as *Enterobacter sakazakii* (Farmer *et al.*, 1980), consists of five species, plus a possible sixth species: *Cronobacter sakazakii*, *Cronobacter malonaticus*, *Cronobacter turicensis*, *Cronobacter muytjensii*, *Cronobacter dublinensis*, and Genomospecies 1 (Forsythe and Varnam, 2009; Iversen *et al.*, 2008). *Cronobacter* species differentiation is primarily based on DNA sequence analysis, supported by biochemical differentiation (Forsythe and Varnam, 2009). *Cronobacter* spp. are considered emerging opportunistic pathogens and the etiological agents of life-threatening infections among infants (Bowen and Braden, 2006; CDC, 2009; Drudy *et al.*, 2006), with the first reported outbreak referring to neonatal meningitis in England in 1958 that resulted in the deaths of two infants (Urmenyi and Franklin, 1961). Few virulence factors have been identified so far (Pagotto *et al.*, 2003; Townsend *et al.*, 2008), though there is evidence of considerable virulence variability among different subtypes of these organisms (Townsend *et al.*, 2008). Owing to their isolation from neonatal infections, the species *Cr. sakazakii*, *Cr. malonaticus*, and *Cr. turicensis* are of particular interest (Forsythe and Varnam, 2009). Despite its low incidence, *Cronobacter* infection, whose main clinical manifestations include meningitis, septicemia, and necrotizing enterocolitis, is associated with significant morbidity (i.e., irreversible neurological sequelae resulting in quadriplegia, developmental impedance, and impaired sight and hearing) and with mortality rates as high as 80% (Drudy *et al.*, 2006). Powdered infant formula (PIF) products have been epidemiologically linked to several cases of *Cronobacter* infection (Bowen and Braden, 2006; CDC, 2009; Himelright *et al.*, 2002; Van Acker *et al.*, 2001), and premature/low-birth-weight infants and those aged less than 28 days are more at risk than older infants due to their underdeveloped immune status and lack of competing intestinal flora (Drudy *et al.*, 2006; Forsythe and Varnam, 2009). Infants of more than 3 months appear to be at considerably less risk for fatal infections (O'Brien *et al.*, 2009), though the few available reports of *Cronobacter* infections in adults usually refer to individuals with underlying diseases (e.g., malignancies) (Drudy *et al.*, 2006). *Cronobacter* spp. are naturally resistant to all macrolides, lincomycin, clindamycin, streptogramins, rifampicin, fusidic acid, and fosfomycin, and the infections associated with these organisms have been traditionally treated with a combination of ampicillin with gentamicin or chloramphenicol (Drudy *et al.*, 2006).

Specific natural reservoirs of *Cronobacter* spp. have not been established yet, with the distribution of these organisms appearing to be ubiquitous. On the basis of their presence in dry herbs and spices, it has been hypothesized that the natural habitat of *Cronobacter* spp. may be plant materials (Chon *et al.*, 2012; Drudy *et al.*, 2006; Hochel *et al.*, 2012; Iversen and Forsythe, 2004). Nonetheless, organisms of the genus *Cronobacter* have also been isolated from animal sources, a wide range of clinical sources (e.g., cerebrospinal fluid, blood, bone marrow, urine, intestinal and respiratory tracts, wounds, and feces), hospital settings, food-processing, and household environments, as well as from multiple food sources (Drudy *et al.*, 2006). *Cronobacter* spp., and primarily *Cr. sakazakii*, have been detected in various food products mainly of plant origin and dried food ingredients (**Table 1**). However, strong association has been observed only with PIF in which the pathogen can be introduced either intrinsically (i.e., at some stage during the manufacturing process) or extrinsically (i.e., during preparation of PIF at hospital neonatal units or at home) (Drudy *et al.*, 2006). As supported by molecular typing data, production facilities may serve as points of continuous entry and dissemination of *Cronobacter* spp. into milk powder products (Lehner *et al.*, 2010). Indeed, studies assessing the occurrence and distribution of the pathogen within milk powder-processing plants have revealed a number of potential reservoirs as well as of practices/events that may compromise the safety of the final product. Potential sources of *Cronobacter* spp. in manufacturing environments are the supply air, spray-drying towers, roller dryers, textile filters for exhaust air, vacuum cleaners, and the filling line of the processing units (Hein *et al.*, 2009; Jacobs *et al.*, 2011; Reich *et al.*, 2010). Long-term persistence of certain *Cronobacter* subtypes in milk powder processing units has been observed in some cases (Craven *et al.*, 2010; Hein *et al.*, 2009). On the basis of the findings of Craven *et al.* (2010), the most prevalent and persistent *Cronobacter* clones were isolated from external roofs above spray dryers, in air treatment areas and where high foot traffic occurs. Practices/events that may result in

contamination of the final milk powder include reintroduction of filtered powder into the product flow, passing of contaminated milk concentrated through the process unheated, and failure of established hygiene measures (e.g., cleaning-in-place events and heat treatments) to completely eliminate *Cronobacter* spp. from all areas of the processing line (Hein *et al.*, 2009; Jacobs *et al.*, 2011). In addition to food-processing facilities, *Cronobacter* spp. have been isolated from various sites in domestic environments (Kilonzo-Nthenge *et al.*, 2012; Molloy *et al.*, 2009). Hence, given this and that the organisms can also be present in the feces or on skin of healthy individuals (Kandhai *et al.*, 2010), in the absence of good hygiene and food handling practices, PIF contamination may also occur during preparation at home.

To reduce the risk of PIF contamination with *Cronobacter* spp., control measures should be in place throughout the food chain. Manufacturers should implement strategies aiming at controlling the initial populations of these organisms and reducing the risks of PIF contamination both during production and at the postprocessing level. PIF products should be formulated in accordance with the Codex Alimentarius Commission Standards (CCFH, 2008), although manufacturers are being encouraged to develop a greater range of commercially sterile alternative formula products specifically targeting high-risk groups (i.e., premature/low-birth-weight infants) (Drudy *et al.*, 2006). With regard to the development and application of control interventions at the manufacturing level, research data suggest that gamma irradiation may be effective against *Cronobacter* spp. in PIF (Osaili *et al.*, 2007), whereas organic acids such as propionic acid and acetic acid may possibly be used as preservatives to inhibit the survival and growth of these organisms in liquid foods (Back *et al.*, 2009). In addition to PIF manufacturers, caregivers in hospital neonatal units as well as food handlers at home are also responsible for the safety of this product, and should be continuously alerted that PIF is not a sterile product, and that, therefore, the use of hygienic measures during preparation is essential (Drudy *et al.*, 2006). Furthermore, given that infant formula can support prolific bacterial growth, appropriate temperature control of reconstituted product is of vital importance for its safety (Forsythe and Varnam, 2009). The World Health Organization (WHO) and the United Nations Children's Fund recommend that, where possible, infants should be exclusively breastfed for the first 6 months of life (WHO/UNICEF, 2003). Furthermore, the WHO in collaboration with the Food and Agriculture Organization (FAO) of the United Nations have issued recommendations regarding the safe preparation, storage, and handling of PIF in both care settings and the home. According to these recommendations, PIF should be reconstituted at 70 °C and either used within 2 h after preparation or stored in the refrigerator ($\leq$5 °C) for up to 24 h; feed that has not been consumed within 2 h should be discarded (FAO/WHO, 2007). Finally, as certain procedural and environmental factors within neonatal intensive care units may have an important effect on infant formula contamination (Steele and Short, 2008), increasing the awareness of the potential threats posed by *Cronobacter* spp. among medical personnel and caregivers via continuous education is of vital importance for protecting high-risk infants (Drudy *et al.*, 2006). With reference to future trends, given that since its initial recognition the incidence of *Cronobacter* in PIF on the market has appeared to decrease, though improvement of hygiene measures has been associated with reduction of reported outbreaks, it has been opined that of particular interest are also powdered nutrition formulas frequently consumed as dietary supplements by the elderly and other immunocompromized individuals, population groups which are also susceptible to *Cronobacter* infections (Forsythe and Varnam, 2009).

Escherichia coli

There are a number of different enteropathogenic groups of *E. coli* that have been shown to cause various types of gastrointestinal infections, with enterohemorrhagic *E. coli* (EHEC) being recognized as an etiological agent of serious illness and mortality in outbreaks of foodborne illness involving a large variety of foods and proceeding to hemolytic uremic syndrome (HUS) (Viazis and Diez-Gonzalez, 2011). A common characteristic of all EHEC strains is their ability to produce shiga toxins, and as such, they are commonly referred to as shiga toxin-producing *E. coli* (STEC) (Viazis and Diez-Gonzalez, 2011). STEC cause sporadic or epidemic foodborne or waterborne illness, whose clinical spectrum involves diarrhea, hemorrhagic colitis, and the potentially fatal HUS (Karmali, 2005). The most common serotype implicated worldwide as the major cause of hemorrhagic colitis and HUS is *E. coli* O157:H7, whose detection and diagnosis is based on its inability to ferment the carbohydrate sorbitol (Bielaszewska and Karch, 2000; Karmali, 2005; Viazis and Diez-Gonzalez, 2011). Since the initial association of *E. coli* O157:H7 with epidemic foodborne disease in 1982, and the consequent definition of a new foodborne zoonosis (Riley *et al.*, 1983), more than 200 different O serogroups of *E. coli* have been shown to produce shiga toxins, and more than 100 of these STEC have been linked to human disease (Johnson *et al.*, 2006). STEC strains capable of fermenting sorbitol have also been isolated from patients and associated with an increasing number of outbreaks and sporadic cases of diarrhea and HUS (Bielaszewska and Karch, 2000). Although their linkage to human disease is not as well understood as that of *E. coli* O157:H7 and their true occurrence is most likely underestimated, the rising public health significance of sorbitol-fermenting STEC has been acknowledged (Bielaszewska and Karch, 2000; Gerber *et al.*, 2002).

Non-O157 shiga toxin-producing Escherichia coli

Non-O157 STEC are a heterogeneous group of organisms consisting of more than 100 serogroups (Bielaszewska and Karch, 2000). The clinical diagnosis of non-O157 STEC can be very challenging because, similar to *E. coli* O157:H7, they are capable of inducing a range of illnesses, including diarrhea, hemorrhagic colitis, and HUS, either as sporadic cases or in the form of outbreaks (Johnson *et al.*, 2006). However, despite the similarities of their clinical manifestations, genomic studies suggest that O157 and non-O157 STEC have different evolutionary histories (Smith and Fratamico, 2012). Although cattle are regarded as the major reservoir for clinically significant non-O157 STEC, other animals such as sheep, goats, deer, and swine may also be carriers of these organisms (Monaghan *et al.*, 2012; Smith and Fratamico, 2012). Outbreaks caused by

this group of STEC have been associated with ingestion of contaminated food and water, as well as with person-to-person contact (Kaspar *et al.*, 2010; Smith and Fratamico, 2012). Non-O157 STEC strains have been linked to major foodborne outbreaks in the USA, Europe, Australia, Japan, and other countries, being often responsible for a considerable portion of the total reported STEC foodborne infections (Kaspar *et al.*, 2010; Scallan *et al.*, 2011; Smith and Fratamico, 2012). Foods that have been associated with illness caused by these organisms include raw and pasteurized cow's milk, ice cream, cheeses, fermented sausages, ground beef, cider, and vegetables (Mathusa *et al.*, 2010; Smith and Fratamico, 2012).

Serogroups that have emerged as significant etiological agents of human disease (both diarrhea and HUS) in several parts of the world include O26, O45, O103, O111, O121, and O145 (Bielaszewska and Karch, 2000; Bielaszewska *et al.*, 2007; Brooks *et al.*, 2005; Brown *et al.*, 2012; CDC, 2013; Gerber *et al.*, 2002; Patton *et al.*, 1996; Vally *et al.*, 2012). Indeed, approximately three-fourths of the disease-inducing non-O157 STEC isolates reported to the Centers for Disease Control and Prevention of the United States Department of Health and Human Services belonged to the above-mentioned six O serogroups (Brooks *et al.*, 2005). Hence, as a result of their increasing public health impact, these six serogroups were declared by the United States Department of Agriculture's Food Safety and Inspection Service as adulterants if present in raw nonintact beef products (USDA-FSIS, 2011). Molecular subtyping data indicate that strains of serogroups O26, O103, and O111 belong to their own clonal lineage and exhibit unique virulence profiles (Bielaszewska and Karch, 2000). Additional non-O157 STEC serogroups that have been reported to emerge in Europe are O100 and O127 (Orth *et al.*, 2006). It has been suggested that certain non-O157 STEC strains (e.g., strains producing shiga toxin 2 (Stx2)) may be more likely to precipitate HUS than others (e.g., strains producing shiga toxin 1 (Stx1) alone) (Brooks *et al.*, 2005; Johnson *et al.*, 2006). Nevertheless, due to the generally limited information that is currently available with regard to the virulence and stress responses of non-O157 STEC, it is difficult to draw solid conclusions on their pathogenicity or their behavior when exposed to stress in the environment, in food, and during food processing (Smith and Fratamico, 2012). It has been opined that the incidence, distribution, and pathological spectrum of these emerging agents is expected to be elucidated only through improved surveillance, with the latter requiring a number of individual conditions to be met including increased clinical suspicion, improved laboratory isolation through the development and use of rapid, sensitive, accurate, and inexpensive techniques, as well as continued serotyping of isolates in public health laboratories (Brooks *et al.*, 2005; Johnson *et al.*, 2006).

Sorbitol-fermenting shiga toxin-producing Escherichia coli *O157:H*$^-$

Sorbitol-fermenting STEC O157:H$^-$ (H$^-$ indicates nonmotility) strains have been identified as agents of severe human disease, such as HUS, with the organisms being isolated throughout Europe including the Czech Republic, Hungary, Finland, and the UK, as well as in Australia (Orth *et al.*, 2009). The first isolation of these organisms was reported during a HUS outbreak investigation in Bavaria, Germany, in 1988; nonmotile *E. coli* strains, harboring the *stx2* gene, and fermenting sorbitol within 24 h of incubation were isolated from the stools of two out of six affected children (Karch *et al.*, 1990). This group of organisms appears to represent a new clone within the *E. coli* O157 serogroup, having its own typical combination of virulence factors (Bielaszewska and Karch, 2000). Indeed, it has been observed that illness associated with sorbitol-fermenting STEC O157:H$^-$ is rarely confined to diarrhea and usually progresses to life-threatening HUS, and that patients infected with these organisms tend to develop HUS more frequently than patients infected with other EHEC strains, indicating a potential hypervirulence of this group of STEC (Nielsen *et al.*, 2011; Orth *et al.*, 2009). Although some epidemiological data indicate potential existence of differential reservoirs of and vehicles of infections caused by STEC O157:H$^-$ in comparison to STEC O157:H7 (Karch and Bielaszewska, 2001), the reservoir and transmission routes of the former organisms are still largely unknown (Orth *et al.*, 2009). Evidence that bovine animals may constitute a reservoir of sorbitol-fermenting STEC O157:H$^-$ and, thus, a source of human disease, has been provided in some cases (Bielaszewska *et al.*, 2000; Orth *et al.*, 2006). Moreover, it has been hypothesized that these pathogens might be adapted to the human intestine and that humans may constitute their primary reservoir; however, the role of person-to-person transmission, which is assumed to be the major route of spreading of STEC O157:H$^-$ infections, still needs to be established (Karch and Bielaszewska, 2001). To properly assess the epidemiological significance of STEC O157:H$^-$ and to better understand its epidemiology, microbiological detection of this pathogen and HUS surveillance need to be improved (Karch and Bielaszewska, 2001; Nielsen *et al.*, 2011). Given that detection of all HUS-causing strains, including the sorbitol-fermenting STEC O157:H$^-$, cannot be assured on the basis of phenotypic characteristics, screening for shiga toxins (e.g., by enzyme-linked immunosorbent assay (ELISA), or shiga toxin genes (e.g., by PCR) is strongly recommended (Orth *et al.*, 2009).

Sorbitol-fermenting shiga toxin-negative Escherichia coli *O157:H*$^-$

Serogroup O157:H$^-$ strains capable of fermenting sorbitol, but not producing shiga toxins, have also been identified as agents of diarrhea and HUS in different countries such as Austria, Germany, and India (Allerberger *et al.*, 2000; Chakraborty *et al.*, 2003; Schmidt *et al.*, 1999). Although their origin, pathogenic mechanisms, and role in human disease warrant clarification, the following hypotheses have been postulated regarding sorbitol-fermenting Stx-negative *E. coli* O157:H$^-$ (Karch and Bielaszewska, 2001): (1) they might have emerged from sorbitol-fermenting STEC O157:H$^-$ organisms by losing their *stx* genes during infection, isolation, or subculture; (2) they might be progenitors of sorbitol-fermenting STEC O157:H$^-$, with the latter arising by transduction with *stx*-converting bacteriophages; and (3) they might be inherently Stx-negative and cause the underlying diseases through the potential possession of additional, as yet unidentified, virulence factor(s).

Mycobacterium paratuberculosis

Mycobacterium avium subspecies *paratuberculosis* (MAP) was first described by Johne and Frothingham in 1895 in the context of an investigation of the cause of chronic diarrhea in cattle, and it has been classified as a member of the family Mycobacteriaceae with the latter consisting of Gram-positive, strictly aerobic, nonmotile, and acid-fast rod-shaped bacteria with fastidious growth requirements (Griffiths, 2009; Legrand *et al.*, 2000). MAP is the etiological agent of paratuberculosis, a chronic granulomatous enteritis in ruminants, also known as Johne's disease, which results in diarrhea, weight loss, and ultimately death (Griffiths, 2009; Skovgaard, 2007). Johne's disease is widespread in dairy cattle and its prevalence is increasing in food-producing animals globally, causing significant financial losses (Greenstein and Collins, 2004; Skovgaard, 2007). Owing to the remarkable clinical, epidemiological, and pathological similarity of Johne's disease to Crohn's disease in humans, a chronic inflammatory disease most commonly affecting the terminal ileum, MAP has also been proposed as the etiological agent of Crohn's disease (Greenstein and Collins, 2004; Griffiths, 2009; Skovgaard, 2007). It has been suggested that multiple interacting factors (genetic predisposition, infectious agents like MAP, alteration of intestinal microflora, and immune-mediated tissue damage) are involved in the development of this disease, with the relative importance of each one of them not being determined (Griffiths, 2009; Pistone *et al.*, 2012). Despite the fact that since the first proposal of a possible link of MAP with Crohn's disease (Chiodini *et al.*, 1984) a considerable amount of data indicating such association has been generated (Feller *et al.*, 2007), a definitive causal relationship has yet to be established (Pistone *et al.*, 2012). Nevertheless, the precautionary principle approach has been advocated until the role of the organism has been definitively determined (Griffiths, 2009), and potential vehicles of transmission of the organism from animals to humans include milk and dairy products as well as raw meat contaminated via feces during slaughtering (Kim and Griffiths, 2011; Skovgaard, 2007). As MAP has been isolated from both raw and pasteurized milk, the efficacy of routine pasteurization against the organism has been questioned (Greenstein and Collins, 2004; Griffiths, 2009; Skovgaard, 2007). However, based on the findings of certain studies, among the numerous studies assessing the ability of MAP to survive pasteurization, it has been concluded that the organism is unable to survive high-temperature short-time (HTST) pasteurization (Griffiths, 2009). Other issues of concern with regard to food safety that warrant further investigation are the ability of MAP to survive the low-temperature thermization processes used in manufacturing of many cheeses, as well as its prevalence and evolution during cheese ripening (Skovgaard, 2007). Additional possible means of transmission of MAP to humans include contaminated water and animal contact (Greenstein and Collins, 2004). The rising concerns regarding the putative zoonotic and foodborne transmission potential of MAP, in conjunction with the difficulties associated with the culture of this organism, render the development of rapid and sensitive methods for its detection and characterization essential (Griffiths, 2009; Kim and Griffiths, 2011; Skovgaard, 2007). Information regarding the relationship between MAP and Crohn's disease, the prevalence and survival of this emerging pathogen in foods and in the environment, as well as potential control approaches has been reviewed in detail by Griffiths (2009).

Salmonella enterica

Salmonellosis, the infection caused by the bacterium *Sa. enterica*, is an illness known for more than 100 years (Bailey *et al.*, 2010). Among the so-called 'host-restricted' *Sa. enterica* serotypes, the ones that are associated with animal hosts (e.g., Gallinarum and Abortusovis) usually elicit very mild symptomatology in humans, whereas, the 'human-restricted' *Sa. enterica* serotypes Typhi, Paratyphi A, and Paratyphi B (which are not usually pathogenic to animals) commonly cause severe systemic disease such as typhoid or enteric fever in humans (Velge *et al.*, 2005). Widespread *Sa. enterica* serotypes, such as Enteritidis and Typhimurium, generally cause gastrointestinal infection to humans, known as nontyphoidal salmonellosis which, however, may also be associated with serious clinical outcomes (e.g., bacteraemia, endovascular infections, and focal infections), particularly in susceptible individuals (Hohmann, 2001; Velge *et al.*, 2005). In addition to host-related factors (e.g., health status, immunosuppresion, age, and genetic defects), the exact clinical outcome of nontyphoidal salmonellosis depends on the virulence traits of the *Sa. enterica* strains responsible for the infection, as certain serotypes of the pathogen are more likely than others to cause systemic infections not only in susceptible hosts, but also in people with no identifiable predisposing conditions (Fierer and Guiney, 2001).

Nontyphoidal *Salmonella* has been a leading cause of foodborne illness in many countries (Adak *et al.*, 2005; Scallan *et al.*, 2011). The emergence of human foodborne infections caused by *Salmonella* Enteritidis and by multiple-antibiotic-resistant strains of *Salmonella* Typhimurium constituted two major changes in the epidemiology of nontyphoidal salmonellosis in the European Union and the USA in the second half of the twentieth century (Velge *et al.*, 2005). Although *Sa. enterica* serotypes Enteritidis and Typhimurium are the serotypes most commonly associated with human infections (CDC, 2011a; EFSA-ECDC, 2012), the emergence and potential connection to human disease of rare serotypes of the organism during the last decades has attracted the attention of the scientific community. For instance, the prevalence, among human clinical cases, of *Sa. enterica* serotype 4,5,12:i:, a serotype antigenically similar and genetically closely related to *Salmonella* Typhimurium, has increased considerably in many countries in the last decade (Soyer *et al.*, 2009). This emerging *Sa. enterica* serotype, which represents multiple distinct clones, has been responsible for a number of human salmonellosis outbreaks (e.g., in Spain, Luxemburg, and the USA) and has been isolated from different foods and animals over the last decades (Soyer *et al.*, 2009). *Salmonella enterica* serotype Cerro has been identified as a potentially emerging pathogen of cattle; given the fact that other *Sa. enterica* serotypes important to bovine health have emerged to become leading causes of human foodborne disease, close monitoring of *Salmonella* Cerro is warranted (Cummings *et al.*, 2010). According to the

findings of a study assessing the association of *Sa. enterica* with foodborne and waterborne diseases in Korea during 1998–2007, although the three most prevalent serotypes were Typhi, Enteritidis, and Typhimurium, there were also remarkable outbreaks caused by rare serotypes such as Othmarschen, London, and Paratyphi A (Kim, 2010). *Salmonella enterica* serotype Napoli is another emerging serotype in Italy, France, and Switzerland; characterization of strains of this serotype isolated in Italy from human cases, foods of animal origin, and the environment showed an array of virulence genes similar to those of other serotypes of public health significance, demonstrating its ability to cause infection in humans (Graziani *et al.*, 2011). Lastly, *Sa. enterica* serotype Weltevreden, which has long been associated with meat products in Southeast Asia, is an emerging serotype associated with meat and particularly with plant products in Western countries (Brankatschk *et al.*, 2012; Emberland *et al.*, 2007). Nonetheless, to enhance one's understanding of the ecology and risk factors for human infection of the aforementioned emerging serotypes, further studies are required.

Streptococcus suis

Streptococcus suis is an encapsulated Gram-positive, facultatively anaerobic coccus which is emerging as an important threat to human health (Segura, 2009; Wertheim *et al.*, 2009). The organism's main reservoir is swine, with its natural habitat being the upper respiratory, genital, and alimentary tracts of pigs (Ma *et al.*, 2008; Segura, 2009). *Streptococcus suis* was first described by veterinarians in 1954 as the etiological agent of outbreaks of meningitis, septicemia, and purulent arthritis among piglets (Field *et al.*, 1954). The first human cases of *St. suis* infection were reported in 1968 in Denmark (Perch *et al.*, 1968), and since then numerous cases have been reported worldwide including the UK, France, Germany, The Netherlands, Sweden, New Zealand, Thailand, Singapore, Taiwan, and Hong Kong (Ma *et al.*, 2008). On the basis of composition of the polysaccharide capsule, 35 serotypes of the organism have been identified, with serotype 2, however, being associated with the majority of cases of human infections (Lun *et al.*, 2007; Wertheim *et al.*, 2009; Segura, 2009). Despite the fact that most reports refer to sporadic cases of infection, an outbreak of acute disease in humans in Sichuan Province, China in 2005, involving 215 cases and 38 deaths, highlighted the importance of *St. suis* as an emerging zoonotic pathogen (Yu *et al.*, 2006). The epidemiology of *St. suis* infections in humans remains largely undefined (Segura, 2009). Nonetheless, and in concordance with the pathogen's natural distribution in the environment, human cases are most frequently reported from countries where pig-rearing is common (particularly in Southeast Asia), and the majority of them are associated with cutaneous contact with infected pigs or with handling or consumption of uncooked or undercooked pork (Segura, 2009; Wangsomboonsiri *et al.*, 2008; Wertheim *et al.*, 2009). *Streptococcus suis* causes systemic infection in humans affecting several organ systems, with its most common clinical manifestation being meningitis, while patients are also likely to develop skin problems (e.g., petechiae, purpura, and ecchymoses) (Wertheim *et al.*, 2009). Less common manifestations of the infection include endocarditis, acute pyogenic arthritis, endophthalmitis and uveitis, peritonitis, rhabdomyolysis, and spondylodiscitis, whereas a striking feature that may be reported by up to one-half of patients is subjective hearing loss (Segura, 2009; Wertheim, *et al.*, 2009). Simple control measures, embraced by both workers with occupational exposures and the general public, should be adequate to prevent the majority of cases of *St. suis* infection. Such measures include cautious handling of pigs or raw pork (e.g., wearing gloves during swine slaughtering or processing of pork meat, hand washing after handling of raw pork meat, and avoiding cross-contamination between raw and cooked pork) and thorough cooking of pork meat (Ma *et al.*, 2008; Segura, 2009; Wertheim *et al.*, 2009). Future research shedding light on the virulence factors, the selective pressures resulting in virulence enhancement, as well as the geographical localization of emerging highly virulent types of *St. suis*, is expected to improve significantly one's understanding of the complex evolution of this pathogen (Segura, 2009).

Antimicrobial-Resistant Strains

The appearance of antimicrobial-resistant bacteria has been promoted by the extensive use or misuse of antimicrobial agents, not only in the treatment of infected humans and animals but also as growth-enhancing or health-promoting agents in livestock, seafood, and plant production (Helmuth, 2000; Hur *et al.*, 2012). The overuse of antimicrobials in animal husbandry may result in a long-lasting, strong selective pressure on bacteria prevalent in intensive production units, leading to the emergence of antimicrobial-resistant strains in food animals, which are then transmitted to humans either directly or through the food supply (Angulo *et al.*, 2000; Fey *et al.*, 2000; Helmuth, 2000). A growing concern over the past 30 years is the worldwide emergence and increasing prevalence of MDR phenotypes among bacterial strains, and particularly among *Sa. enterica* serotypes, exhibiting resistance to several clinically important antimicrobial agents traditionally used to treat bacterial infections in human and veterinary medicine (Hur *et al.*, 2012). The first reports on resistant *Salmonella* date back to the early 1960s and refer mainly to monoresistant strains of the organism (Helmuth, 2000). Widespread resistance of *Sa. enterica* serotypes Typhi and Paratyphi A to chloramphenicol, ampicillin, and cotrimoxazole was documented at the end of the 1980s and early 1990s with MDR isolates of these serotypes causing significant outbreaks, particularly in Asia (Parry *et al.*, 2002). Nonetheless, the declining resistance levels as observed and reported in the following years suggested that drugs such as chloramphenicol may be used again as first-line therapy for enteric fever (Parry, 2003). Low-level resistance to ciprofloxacin in the aforementioned serotypes has been reported in areas of Central, South and Southeast Asia, frequently resulting in fluoroquinolone treatment failures (Aarestrup *et al.*, 2003; Parry *et al.*, 2002). With reference to nontyphoidal *Salmonella*, MDR strains have been found to be of various serotypes including Agona, Anatum, Choleraesuis, Derby, Dublin, Heidelberg, Kentucky, Newport, Pullorum, Schwarzengrund, Seftenberg, Typhimurium, and Uganda (Hur *et al.*, 2012; Wasyl and Hoszowski, 2012). Antimicrobial

resistance has generally been less of a problem in *Sa. enterica* serotype Enteritidis (Hur *et al.*, 2012; Parry, 2003). An event of major public health significance has been the emergence and clonal spread of certain MDR genotypes, with the most characteristic example being the global epidemic spread of *Sa. enterica* serotype Typhimurium definitive type 104 (DT104) (Butaye *et al.*, 2006). This phage type commonly exhibits the following pentaresistance pattern (i.e., resistance to five antimicrobial agents): ampicillin, chloramphenicol, streptomycin, sulfamethoxazole, and tetracycline (R-type ACSSuT) (Helmuth, 2000; Hur *et al.*, 2012; Parry, 2003). Additional resistance to trimethoprim and low-level resistance to ciprofloxacin have also been occasionally observed among *Salmonella* Typhimurium DT104 isolates (Parry, 2003; Velge *et al.*, 2005).

The ability to produce β-lactamases (i.e., enzymes that hydrolyze β-lactams) constitutes one of the most important resistance mechanisms of Gram-negative rods, and the emerging resistance related to the production of extended-spectrum β-lactamases (ESBLs) has been identified as a significant problem with regard to handling of bacterial infections (Gniadkowski, 2001; Paterson, 2006). ESBLs are mainly found in strains of *E. coli* and *Klebsiella pneumoniae*, but are also reported in other members of the family Enterobacteriaceae as well as in *Pseudomonas aeruginosa*, and infections with ESBL-producing bacterial strains are mainly encountered, sporadically or in outbreaks, in critical care units in hospitals (Shah *et al.*, 2004). ESBLs are typically plasmid, rather than chromosomally mediated enzymes, and the majority of them have evolved from class A β-lactamases, namely TEM-1, TEM-2, and SHV-1, which are frequently expressed in Gram-negative bacteria and confer resistance to ampicillin, amoxicillin, and other penicillins, as well as to early generation cephalosporins (Paterson, 2006; Shah *et al.*, 2004). TEM- or SHV-type ESBLs are typically not active against cephamycins or carbapenems, and can generally be inhibited by β-lactamase inhibitors (e.g., clavulanate, sulbactam, or tazobactam) (Paterson, 2006). Persistent exposure of bacterial strains to a multitude of β-lactams has induced dynamic and continuous production and mutation of β-lactamases of certain strains, expanding their activity even against newly developed β-lactam antibiotics (Shah *et al.*, 2004). For instance, mutations of the genes encoding TEM-1, TEM-2, or SHV-1 gave rise to new β-lactamases, capable of hydrolyzing third-generation cephalosporins and aztreonam (Paterson, 2006). Additional families of ESBLs that may also be expressed by Enterobacteriaceae include the CTX-M-type (cefotaximases) and OXA-type (primarily in *P. aeruginosa*) enzymes as well as novel unrelated β-lactamases (Jin and Ling, 2006; Paterson, 2006; Shah *et al.*, 2004). In addition to ESBLs, other β-lactamases capable of hydrolyzing extended-spectrum cephalosporins are: (1) class C cephalosporinases (AmpC) which, unlike ESBLs, are also active against cephamycins and resistant against β-lactamase inhibitors and (2) carbapenemases that have a broader range of activity and are also active against carbapenems (Gniadkowski, 2001; Paterson, 2006).

There is ample evidence of person-to-person transmission with regard to β-lactamase producers (Paterson, 2006). Furthermore, although β-lactamase-producing bacterial strains are mainly prevalent in hospital settings, there is evidence suggesting that they also are emerging and spreading in the community, with community-acquired cases of infections including both urinary tract and gastrointestinal infections (Paterson, 2006). β-lactamase-producing bacteria that have been associated with drug-resistant gastroenteritis include *Sa. enterica*, *Shigella* spp., *Vibrio cholerae*, and STEC (Paterson, 2006). With reference to *Sa. enterica*, both ESBLs and AmpC β-lactamases have been identified, and the resistance of this pathogen to third-generation cephalosporins is of great concern as ceftriaxone constitutes the antimicrobial of choice for treating invasive salmonellosis caused by MDR strains in children (i.e., where the use of quinolones is not indicated) (Butaye *et al.*, 2006; Paterson, 2006; Velge *et al.*, 2005). The emergence and worldwide increase of ESBL (particularly of the CTX-M group) producers among *Sa. enterica* serotypes, including the serotypes Enteritidis, Typhimurium, and Virchow, has been acknowledged as an important public health issue during the last years (Bonalli *et al.*, 2011; Jin and Ling, 2006; Riano *et al.*, 2009). Although more research is required in order to track the evolution of ESBLs in *Sa. enterica* isolates from different environments, some findings do support the potential for clonal spread of CTX-M-type ESBLs among animals and humans (Riano *et al.*, 2009). Furthermore, *Sa. enterica* serotype Newport isolates resistant to multiple antimicrobials, including extended-spectrum cephalosporins via the production of AmpC, known as serotype Newport MDR-AmpC isolates, have recently emerged. The common recovery of MDR-AmpC isolates of *Salmonella* Newport from food animals and humans suggests their potential transmission to humans through the food chain (Zhao *et al.*, 2003). Indeed, as supported by epidemiological data, infections with such isolates appear to be acquired through the food supply, most likely from bovine and perhaps poultry sources, and particularly among individuals already taking antimicrobial agents (CDC, 2002; Varma *et al.*, 2006). The emergence and worldwide dissemination of multiresistant *E. coli* producing ESBLs, particularly of the CTX-M-type, as an important cause of both nosocomial and community-onset infections have also been acknowledged (Oteo *et al.*, 2010; Pitout *et al.*, 2004). Similar to the case of *Sa. enterica*, the rising trend of antimicrobial resistance and the high prevalence of β-lactamase determinants in *E. coli* strains of animal origin (Li *et al.*, 2010) dictate the development and implementation of effective control interventions.

Surveillance programs, at both national and international levels, have been proven to be valuable tools for ensuring prudent use of antimicrobials in livestock and veterinary medicine as well as for monitoring the appearance of antimicrobial resistance (Hur *et al.*, 2012; Parry, 2003). In addition to appropriate antibiotic management, improved vaccines and diagnostics as well as adherence to infection control measures (e.g., use of gloves and adequate hand hygiene in health care settings) may also be needed in order to address this public health and food safety issue (Hur *et al.*, 2012; Oteo *et al.*, 2010; Paterson, 2006). Moreover, continued research on the genetic determinants of antimicrobial resistance (e.g., plasmid sequencing projects) and on the ecology, epidemiology, and evolution of MDR strains is expected to provide a better understanding of the emergence and distribution of antimicrobial resistance, and, therefore, to allow for the design of improved control measures (Alcaine *et al.*, 2007; Louden *et al.*, 2012).

Other Bacteria

Although its foodborne pathogen status has been well-established, constituting the leading cause of sporadic bacterial gastroenteritis, *Ca. jejuni* has also been recognized as one of the most prevalent and serious emerging bacterial pathogens of meat, poultry, and derived products (Mor-Mur and Yuste, 2010). Its low infectious dose (i.e., less than 100 cells can cause disease) and its ability to survive refrigeration and freezing delineate the relevance of this organism to food safety and public health, with raw or undercooked poultry being the primary source of campylobacteriosis (Mor-Mur and Yuste, 2010). Complications of campylobacteriosis include reactive arthritis, pancreatitis, meningitis, endocarditis, and the Guillain–Barré syndrome, a disorder of the peripheral nervous system, with the latter being primarily associated with serotypes O:19, O:4, and O:1 of the pathogen (Mor-Mur and Yuste, 2010). Owing to difficulties associated with culturing of *Ca. jejuni*, it has been opined that the incidence of campylobacteriosis in the past was most likely underestimated, with foodborne outbreaks being erroneously identified as caused by other organisms such as *Salmonella* spp. (Mor-Mur and Yuste, 2010).

Bacterial species belonging to the genus *Helicobacter* have also been identified as potentially emerging foodborne pathogens. One such example is *Helicobacter pylori*, which, since its initial recognition in 1982, has been implicated as the etiological agent of gastritis and as a major contributing factor in the development of peptic gastroduodenal ulcers (Gracey, 1994; Meng and Doyle, 1998). Although humans were originally thought as the only natural host of *H. pylori*, the organism has also been isolated from nonhuman primates, suggesting that it may be a zoonotic pathogen with its transmission occurring from animals to humans (Meng and Doyle, 1998). Additional modes of *H. pylori* transmission that have been proposed include fecal–oral transfer and person-to-person spread (Gracey, 1994), though there is also evidence supporting the hypothesis of waterborne transmission (Meng and Doyle, 1998). Nevertheless, the significance of this organism as a foodborne pathogen has not been firmly established yet. *Helicobacter pullorum* is another species of potential importance as an emerging foodborne pathogen; it has been associated with diarrhea, gastroenteritis, and liver diseases in humans, to which it may be transmitted via consumption of undercooked poultry products (Skovgaard, 2007).

In addition to the aforementioned bacterial pathogens, attention should be paid to well-established foodborne pathogens, which, however, appear to reemerge exhibiting additional characteristics/abilities (e.g., higher virulence or lower infectious dose) or being associated with other, frequently unexpected, food vehicles. Examples of such foodborne pathogens are *Sa. enterica* and *Listeria monocytogenes*. Recent salmonellosis outbreaks have been associated with unexpected food products such as microwavable, ready-to-cook foods, breaded (sometime prebrowned) chicken nuggets, and chicken entrees, as well as peanut butter, demonstrating that the landscape of foodborne infections is in flux (Tauxe *et al.*, 2010). Furthermore, both *Sa. enterica* and *L. monocytogenes*, as well as other established foodborne pathogens, have been increasingly associated with illness outbreaks linked to consumption of fresh produce (CDC, 2011b, 2012; Tauxe *et al.*, 2010). For instance, an unusually large listeriosis outbreak associated with cantaloupe was reported in 2011 in the US (CDC, 2011b); this was the first epidemiologic association of *L. monocytogenes* with melon, whereas a novel serotype 1/2a outbreak strain and two novel epidemic clones of the pathogen were identified during the outbreak investigation (Lomonaco *et al.*, 2013).

Viruses

Various groups of viruses are well recognized as important agents of waterborne and foodborne illness. Among these, the gastroenteritis-causing noroviruses (NoVs) and hepatitis A virus have been identified as the most important foodborne pathogens on the basis of their highly infectious nature, and the large numbers of outbreaks and people affected (Duizer and Koopmans, 2009; Koopmans and Duizer, 2004). Despite the well-established foodborne pathogen status of certain viral agents, such as the above two groups, foodborne viruses can be regarded as an emerging problem as a whole, due to the decrease in immunity of populations in countries with high standards of hygiene observed in recent years (Koopmans and Duizer, 2004). In general, a definitive association of direct or indirect animal contact with foodborne infection in humans has not been established, and most documented foodborne viral outbreaks can be traced to foods that have been manually handled by infected food handlers (symptomatic or not) and not heated or minimally processed afterwards (Koopmans and Duizer, 2004). Although most frequently observed at the end of the food chain, viral contamination of food can occur anywhere in the process from farm to fork, and a wide variety of food items have been associated with epidemic disease including deli meats, sandwiches, bakery products, berries, dishes containing fresh (or fresh frozen) fruits and vegetables, and, most importantly, shellfish (Koopmans and Duizer, 2004). Given that viruses, unlike bacteria, are strict intracellular pathogens (i.e., cannot replicate in harvested or processed food), and, thus, viral contamination of food is not expected to increase during processing, transport, or storage, the emphasis with regard to their control should be placed on prevention of contamination by proper implementation of good hygiene practices, good manufacturing practices, and Hazard Analysis and Critical Control Points programs (Koopmans and Duizer, 2004). With reference to recommended areas for future research, these include development of simple, efficient, and reproducible detection methods of viruses in foods, assessment of viral survival on different food commodities, and determination of the duration and levels of shedding of viral pathogens in people with and without symptoms (Koopmans and Duizer, 2004).

As viruses causing gastroenteritis have been well recognized as among the most common causes of foodborne illness worldwide, with NoVs ranking number one in many industrialized countries (Duizer and Koopmans, 2009), they will not be further discussed in this article. The information provided in the following sections refers to viral pathogens that are or have the potential to be foodborne, and that would better fit the term 'emerging.'

Hepatitis Viruses

The enterically transmitted hepatitis viruses are transmitted by the fecal–oral route, either directly from person to person or indirectly when water or food contaminated with fecal material is ingested, and replicate and cause disease in the liver (Mattison *et al.*, 2009). The hepatitis A virus (HAV) is a member of the Picornaviridae family, in the genus Hepatovirus, and consists of nonenveloped, icosahedral capsids of approximately 30 nm in diameter enclosing a 7.5 kb single-stranded, polyadenylated RNA genome (Mattison *et al.*, 2009). The incidence and severity of HAV infection may vary considerably both among and within countries. In many developing regions of the world where hygienic standards (i.e., clean water, sewage systems, and proper hygiene practices) may be below acceptable standards, HAV infection is endemic, with the majority of people being infected in early childhood and virtually all adults appearing to be immune; in these areas, HAV transmission occurs primarily from person to person, and outbreaks are not that common as most infections occur among children, who generally remain asymptomatic (Koopmans and Duizer, 2004; Mattison *et al.*, 2009). In contrast, in the developed countries, where HAV endemicity is low, the majority of adults are susceptible to HAV infection, and HAV constitutes a serious and increasing public health concern (Koopmans and Duizer, 2004; Mattison *et al.*, 2009). Viral hepatitis, which is generally an acute infection but its resolution provides life-long immune protection against future infections, is characterized by fever, jaundice, light-colored stools, dark-colored urine, abdominal pain, and occasional diarrhea (Mattison *et al.*, 2009). As virus shedding may start 10–14 days before the onset of symptoms, HAV spreading can be extensive (Koopmans and Duizer, 2004). Although the accurate identification of foodborne sources of HAV infection is frequently difficult due to the long incubation period between infection and symptomatic disease, foodborne outbreaks of HAV have been associated with many different food types, and primarily with shellfish (due to fecal contamination of shellfish growing waters) and fresh or frozen produce (Mattison *et al.*, 2009).

Hepatitis E virus (HEV) is a member of the genus Hepevirus in the Hepeviridae family, with its particle being a nonenveloped icosahedron of approximately 30 nm in diameter and its genome a 7.5 kb single-stranded RNA molecule (Mattison *et al.*, 2009). Although HEV is known for its ability to cause acute clinical hepatitis, primarily as waterborne outbreaks and sporadic infections, in young adults throughout the developing world, there are recent reports on zoonotic foodborne autochthonous HEV infections in developed countries (Khuroo and Khuroo, 2008; Nicand *et al.*, 2009). In this sense, hepatitis E is regarded as an emerging concern in western countries (i.e., Western Europe, North America, Japan, and Australia), and considerable advances have been successful in understanding its epidemiology (Mattison *et al.*, 2009; Khuroo and Khuroo, 2008). Emerging HEV infections in the developed world have been more frequently associated with people of advanced age (i.e., more than 50 years) (Mattison *et al.*, 2009; Nicand *et al.*, 2009). In addition to its well-established waterborne transmission, HEV may be transmitted to humans via the following routes: (1) consumption of raw or undercooked meat of naturally infected wild (e.g., boar and deer) and domesticated (e.g., pigs) animals; (2) occupational exposure to infected animals; (3) parenteral transmission; and (4) vertical transmission from mother to child (Khuroo and Khuroo, 2008; Nicand *et al.*, 2009). The incubation period of HEV varies from 15 to 45 days, and the typical clinical symptoms of the infection are similar to those associated with HAV infection and include jaundice, dark urine, enlarged tender liver, elevated liver enzymes, abdominal pain, and tenderness accompanied by nausea, vomiting, and fever (Khuroo and Khuroo, 2008). Nevertheless, the disease may vary in severity and is often complicated by protracted coagulopathy and cholestasis, whereas chronic HEV infection, chronic hepatitis, and cirrhosis have been frequently reported in organ transplant recipients (Khuroo and Khuroo, 2008). High rates of fulminant hepatitis and fatality have been documented for classical HEV infections in pregnant women, particularly in the third trimester (Mattison *et al.*, 2009).

Other Viruses

In addition to the discussion above in Section Hepatitis Viruses, there are also some emerging viruses that, although not usually transmitted via the fecal–oral route, may infect via the gastrointestinal tract and have the potential to emerge as food safety concerns. These viruses are avian influenza viruses, the coronavirus, and the tick-borne encephalitis virus (Mattison *et al.*, 2009).

The avian influenza virus A genus is classified in the family Orthomyxoviridae and is characterized by pleomorhpic, enveloped virions with a segmented single-stranded RNA genome. The viruses of this genus are classified into subtypes based on the two envelope glycoproteins, the hemagglutinase (H type) and the neuraminidase (N type), and there are 16 known H types and 9 known N types (Mattison *et al.*, 2009). All of the known subtypes of influenza A viruses have been found in birds, and viruses containing combinations of the H1, H2, H3, N1, and N2 types are considered to be established in the human population, whereas viruses of the H5, H7, and H9 subtypes have been associated with sporadic human infections (Mattison *et al.*, 2009). Humans acquire avian influenza viruses primarily through direct contact of the mucous membranes with infectious secretions and excreta from infected birds or contaminated poultry products (Doyle and Erickson, 2006). An avian influenza virus subtype that has recently attracted the attention of public health authorities is the highly pathogenic H5N1 virus, which has been detected in poultry from more than 50 countries and it has infected humans in Vietnam, Thailand, Indonesia, Cambodia, China, Turkey, Iraq, Azerbaijan, Egypt, and Djibouti (De Jong and Hien, 2006; Mattison *et al.*, 2009). This virus replicates to extremely high levels in the upper respiratory tract, causing an intense inflammatory response, and is associated with a particularly high case fatality rate, frequently more than 60% (De Jong *et al.*, 2006). Despite its limited ability to spread from person to person, there is concern that H5N1 virus could acquire the ability to spread effectively in humans and result in a worldwide pandemic (Mattison *et al.*, 2009). Although almost all H5N1 infections of humans have been linked to close contact with infected poultry (De Jong and Hien, 2006), given that the virus has been isolated from various parts of infected

poultry such as the blood, bones and meat, the consumption of raw or undercooked poultry products as a potential source of infection cannot be renounced (Mattison *et al.*, 2009).

Although coronaviruses typically cause mild respiratory disease, a particularly virulent strain, known as the 'sudden acute respiratory syndrome coronavirus,' emerged in 2003, causing more than 8000 cases of systemic infections as well as respiratory illness, and being associated with an approximately 10% case fatality rate (Mattison *et al.*, 2009; Wang and Chang, 2004). The fact that this virus was isolated from the digestive tract, as well as from feces and sewage, raises the possibility that it may have had the potential to be transmitted through the fecal–oral route and food products (Mattison *et al.*, 2009). The tick-borne encephalitis virus is considered endemic to Europe, and is usually transmitted to humans by tick bites; nonetheless, some cases have been linked to the consumption of raw milk from infected cattle or goats (Mattison *et al.*, 2009). Finally, additional emerging viruses of interest are the gastroenteritis-causing parvoviruses, toroviruses, and picobirnaviruses (Mattison *et al.*, 2009).

Parasites

Waterborne and foodborne parasitic infections have received considerable attention in the last decade. Despite the fact that many of these infections are well recognized for many years, they are considered emerging as a result of either true higher incidence or higher detection (Dorny *et al.*, 2009). Factors that can be associated with increased human exposure to foodborne parasites and, thus, with the emergence or reemergence of many foodborne parasitic diseases as this has been documented recently on a worldwide basis, include changing eating habits (e.g., increased demand for exotic and raw food), population growth and particularly increase of population of highly susceptible people, increased international travel, globalization of food supply, changes in food production systems, climate changes, and improved diagnostic tools (Broglia and Kapel, 2011; Dorny *et al.*, 2009). A characteristic example is that of the increasing development of certain farming practices such as aquaculture, driven by the rising global demand for protein of animal origin, in developing countries where the existing health monitoring practices may not be sufficient or adequately implemented (Broglia and Kapel, 2011). It has been acknowledged that there is an urgent need for better monitoring and control of foodborne parasites, and some of the suggested means for achieving this are the use of new risk assessment tools, the development and utilization of new monitoring technologies (both serological and molecular), as well as health education (Dorny *et al.*, 2009). In general, given that foodborne parasitic infections are actually reflecting a complex system of interconnected biological, economic, social, and cultural variables, it has been proposed that their control should be based on a holistic approach, with the latter, however, requiring a large amount of high-quality data as well as systematic collaboration across sectors and disciplines (Broglia and Kapel, 2011). The information provided below refers to emerging parasites that have been associated with human infections and are or have the potential to be foodborne.

Cyclospora cayetanensis

Cyclospora cayetanensis is a single-cell coccidian protozoan, which has been implicated as the etiological agent in cases of watery diarrhea, nausea, vomiting, fatigue, and anorexia in humans and other primates (Dorny *et al.*, 2009; Rose and Slifko, 1999). Despite the fact that the infection is generally treatable with none or mild symptomatology in the immunocompetent, it may be associated with a profuse and prolonged (lasting for several months) diarrhea in immunocompromized individuals (Rose and Slifko, 1999). Outbreaks of *Cy. cayetanensis* infection have been increasingly observed since the 1990s, particularly in North America and Asia (Dorny *et al.*, 2009). Although traditionally regarded as a waterborne parasite, outbreaks of *Cy. cayetanensis* infections have also been linked to various fresh fruits, vegetables, and herbs such as blackberries, raspberries, strawberries, lettuce, and basil (Dorny *et al.*, 2009; Rose and Slifko, 1999; Smith and Evans, 2009).

Cryptosporidium and Giardia

The parasites of the genera *Cryptosporidium* and *Giardia* are well-recognized causes of protozoan waterborne diseases known as cryptosporidiosis and giardiasis, respectively. Owing to their extensive genetic diversity, the taxonomy of these parasites has frequently been a matter of debate (Dorny *et al.*, 2009). In spite of the fact that these parasites have been primarily associated with waterborne outbreaks and with infections contracted via animal handling or contact with children, they may also contaminate food commodities (e.g., soft fruits and vegetables, and shellfish) and cause infections in humans by these routes (Dorny *et al.*, 2009).

Cryptosporidium is a coccidian parasite that infects a wide range of vertebrate hosts including mammals, rodents, birds, reptiles, and fish (Smith and Evans, 2009). This parasite has emerged as an important pathogen of humans in the last 25 years, with eight described and five undescribed species potentially infecting immunocompetent and immunocompromized humans. Among these species, *Cryptosporidium hominis* and *Cryptosporidium parvum* are the most commonly detected, though the latter is the best studied species and has been identified as a major zoonotic pathogen and a significant contributor to environmental contamination with oocysts (Smith and Evans, 2009). Cryptosporidiosis is a cholera-like disease, its main symptoms are large volumes of fluid loss, fever, and abdominal pain, and its mortality rate can be high (i.e., 50%–60%) in the immunocompromized population (Rose and Slifko, 1999). Foods that have been (or suspected to be) linked to foodborne outbreaks of cryptosporidiosis include apple cider, chicken salad, and cow's milk (Smith and Evans, 2009).

The genus *Giardia* includes species that are host specific (infecting rodents, amphibians, birds, great blue herons, the prairie vole and mammals), as well as species that have zoonotic potential. The parasites that infect humans belong to the species *Giardia duodenalis*, formerly also known as *Giardia intestinalis*, and *Giardia lamblia* (Smith and Evans, 2009). The most common symptoms of giardiasis are diarrhea followed by flatulence and cramps (Rose and Slifko, 1999). Examples of foodstuffs that have been associated with documented outbreaks of giardiasis are Christmas pudding, fruit salad,

home-canned salmon, ice, noodle salad, raw sliced vegetables, sandwiches, and tripe soup, and food handlers have been identified in most of the cases as the most likely source of food contamination (Smith and Evans, 2009).

Toxoplasma gondii

Toxoplasma gondii is a coccidian protozoan parasite of man and animals with a worldwide distribution, constituting one of the most significant parasitic pathogens in Europe and the USA (Mead *et al.*, 1999; Vaillant *et al.*, 2005). Although it has a disease burden similar to that of salmonellosis and camplylobacteriosis, toxoplasmosis (i.e., the disease caused by *T. gondii*) is still regarded as a considerably underreported disease (Dorny *et al.*, 2009). On the basis of multilocus restriction fragment length polymorphism techniques, there are three genotypes within *T. gondii* (genotypes I, II, and III) which correlate with different patterns of human disease, with, however, the majority of human toxoplasmosis cases being associated with genotype II (Smith and Evans, 2009). Toxoplasmosis in immunocompetent hosts is either asymptomatic or associated with nonspecific clinical symptoms such as pyrexia, lymphadenopathy, malaise, and myalgia (Smith and Evans, 2009). Nonetheless, the disease can be severe and is generally considered as a serious health problem in pregnant women, who can pass the infection to the fetus, as well as in immunocompromized people (e.g., acquired immunodeficiency syndrome patients, organ and bone marrow transplant recipients, those with malignancies and on anticancer chemotherapy) (Dorny *et al.*, 2009; Smith and Evans, 2009).

Human toxoplasmosis can be contracted by the ingestion of sporulated oocysts present in cat feces and the environment (Dorny *et al.*, 2009). Furthermore, *T. gondii*, by being a zoonotic parasite present worldwide, has been detected in many animals used for meat production; viable parasites have been isolated from the meat of game, sheep, goat, horse, chicken, and pig (Dorny *et al.*, 2009; Smith and Evans, 2009). With particular reference to swine, a reemergence of toxoplasmosis has been observed in pigs raised in organic farms with outdoor access (Kijlstra *et al.*, 2004). Hence, *T. gondii* can also be transmitted to humans by consumption of raw or undercooked meat contaminated with tissue cysts of the parasite (Dorny *et al.*, 2009; Smith and Evans, 2009). Indeed, foodborne outbreaks of toxoplasmosis have been frequently linked to raw or rare meat, whereas additional food products associated with human infections include raw liver, goat's milk and ice cream (Smith and Evans, 2009). Nevertheless, as supported by epidemiological data, consumption of unwashed fresh vegetables or fruit has also been identified as an important risk factor with regard to toxoplasmosis (Dorny *et al.*, 2009).

Trichinella spp.

Trichinella spp. are zoonotic pathogens with widespread distribution and have been recognized as important agents of meat-borne parasitic infections in humans for a long time. The disease caused by the nematodes of the genus *Trichinella*, referred to as trichinellosis, is contracted in humans by the ingestion of larvae of the parasite that are encysted in muscle tissue of domestic or wild animal meat, with the domestic pig being identified as the most important source of the infection worldwide (Dorny *et al.*, 2009). Although, until recently, all cases of infections in both animals and humans were attributed to the species *Trichinella spiralis*, eight species and four genotypes are today recognized in the genus *Trichinella* (Dorny *et al.*, 2009). Clinical disease in humans is characterized by an intestinal phase and a subsequent parenteral (tissue) phase. Adult worms in the intestine may cause diarrhea, nausea, vomiting, fever, and abdominal pain, whereas the parenteral phase is usually accompanied by heavy muscle pains, fever, and eosinophilia (Dorny *et al.*, 2009; Murrell and Crompton, 2009). Potential complications attributed to larvae of the parasite during the early parenteral phase include facial edema, skin rash, convulsions, weight loss, meningitis, encephalitis, and vertigo, whereas death may also occur in heavily infected individuals (Murrell and Crompton, 2009).

Other Parasites

In addition to the parasites mentioned above, the taeniid tapeworms of the genus *Taenia* are also important zoonotic pathogens likely to be transmitted by food, and particularly by meat, to humans. More specifically, the species *Taenia saginata* (main reservoir: cattle), *Taenia saginata asiatica* (main reservoir: swine), and *Taenia solium* (main reservoir: swine) are the species that have been associated with human infections, and the terms cysticercosis and taeniosis refer to infections with larval and adult tapeworms, respectively (Dorny *et al.*, 2009). *Taenia saginata* is a cosmopolitan parasite found in both industrialized and developing countries; whereas *T. saginata asiatica* (which, although genetically is considered a subspecies of *T. saginata*, has distinct morphological and biological characteristics) is restricted to Asian countries (Dorny *et al.*, 2009). Intestinal taeniosis is usually contracted as the result of consumption of raw or undercooked meat, liver, or viscera, and may cause abdominal discomfort, nausea, weight loss, and occasionally more severe symptoms such as intestinal perforation and peritonitis (Dorny *et al.*, 2009).

Additional emerging parasites with a foodborne transmission potential are the intestinal trematodes of the genera *Fasciola* and *Fasciolopsis*. These parasites, and particularly the species *Fasciola hepatica*, *Fasciola gigantica*, and *Fasciolopsis buski*, may have a significant impact on the livestock sector, and cause infections in humans that are usually acquired by consumption or handling of freshwater aquatic plants (e.g., watercress and water chestnut) (Dorny *et al.*, 2009; Murrell and Crompton, 2009). Moreover, parasites that have recently gained interest are *Trypanosoma cruzi* and *Echinococcus* spp. (especially *Echinococcus granulosus* and *Echinococcus multilocularis*); infective stages of these parasites may be shed in the environment via feces and contaminate foods such as vegetables, fruits, or fruit juices (Dorny *et al.*, 2009). Finally, there is a wide variety of parasites including trematodes, cestodes, nematodes, and pentastomides that can be transmitted to humans by fish, crustaceans, reptiles, amphibians and snails when the meat of these animals is consumed raw or undercooked. Although, traditionally, such parasitic zoonoses are

most common in Asian countries (due to their particular culinary habits and the importance of aquaculture), some of them may emerge in other countries as a result of aquaculture, improved transportation and distribution systems, and tourism (Dorny *et al.*, 2009).

Concluding Remarks

Emerging foodborne pathogens, including bacteria, viruses, and parasites, are undoubtedly one of the most important food safety concerns for the food industry and public health authorities. As proposed by Buchanan (1997) several years ago, there are three research areas of interest with regard to emerging pathogens, which are still relevant and include: (1) research seeking improvements or alternatives to detect and control emerging pathogens; (2) research aiming at reducing the response between the emergence of a pathogen and its control; and (3) research identifying factors that will allow new food safety threats to be anticipated. In general, the challenge of foodborne pathogen emergence is expected to be successfully handled primarily via the development and implementation of robust and effective surveillance programs; such programs will allow for early detection and investigation of emerging (or reemerging) foodborne diseases and for the use of effective strategies for their control and prevention. Furthermore, food safety education of food handlers and consumers and prudent use of antimicrobials also are important for the control of emerging pathogens. Finally, the development and utilization of novel molecular techniques for studying foodborne pathogens, as this has been observed in the past decade, is expected to provide information that will improve one's understanding of the factors underlying the emergence of foodborne pathogens.

Introduction

In recent years, consumers have become increasingly concerned about the safety and quality of their food supply. To ensure that food supplies meet the highest standards of safety and nutritional quality, robust and state-of-the-art analytical methods are essential for all food products. The rapid growth of novel raw materials and ingredients, and new processes in the food industry has also brought new challenges to food scientists. The progresses in food science and technology have driven analytical methods toward those that heavily rely on instrumentation and biochemistry, which provide higher sensitivity and accuracy. Advances in modern food analysis technologies have allowed scientists in food safety and quality to meet such new challenges and demands.

Food analysis is particularly complex due to the intricate food system, which includes key physicochemical and biological characteristics of raw materials, potential existence of microorganisms, different contaminants and additives, and the processing techniques used. For these reasons, various analytical methods have been required for the quality control of foods and selection of appropriate techniques and methodologies are required to obtain the best results. In general, the choice of an analytical technique depends on the purposes of the analysis and the properties of the food. This article attempts to cover the recently developed technologies, as well as traditional instrumentation, techniques, and applications in food analysis.

Food Composition

Food, a highly complex system, contains essential nutrients such as water, carbohydrates, lipids, proteins, vitamins, minerals, and dietary fibers (Eastwood and Kritchevsky, 2005; Williams, 1995). Recent findings about the beneficial roles of nonessential micronutrients, such as polyphenols and carotenoids, to health have led to greater needs for more sophisticated analytical methods. In addition to chemical components, live microorganisms, such as those in fermented foods like probiotic yogurt, can also be a target of the analysis. All these contribute to the increased complexity of the food systems that are analyzed. To gain a meaningful insight into the analysis of these compositions, the aforementioned macronutrients and micronutrients are briefly discussed in this section.

Water

Water, the most abundant substance in nearly all food, plays an important role in the food system. Even pure substances such as sugar and salt contain a small amount of water absorbed on the surface of the crystal. Moisture content is one of the quality factors for food products, especially for dried goods such as milk powder, dehydrated vegetables and fruits, and flours. A reduced moisture content is beneficial for the packing and transportation of food (Slade *et al.*, 1991), as it inhibits microbial growth. However, certain amount of water is essential to make a food fresher and tender.

Moreover, water may be present in the food system as free liquid in which nutrients are dissolved, hydrated, imbibed in gels, or adsorbed on the surfaces of other materials (Levine and Slade, 1991). A method for moisture analysis must therefore depend upon the form of the water present as well as the amount in a particular food.

Carbohydrates

Carbohydrates are an important nutrient that supplies abundant energy and serves as a source of many physiologically active compounds. In general, carbohydrates are divided into three subgroups: monosaccharides, oligosaccharides, and polysaccharides. Carbohydrate analysis is a key quality assurance tool for food processing, not only because it ensures that the amount of ingredients added into the food meet the standards or claims on the label, but it is also a means to detect food deterioration. Moreover, low-caloric sweeteners, such as sugar alcohols and rare sugars, D-psicose and D-tagatose, became increasingly important to consumers and the need for specific analytical methods for these carbohydrates has also been recognized. Another significant outcome of carbohydrate analysis is calorie calculation.

Proteins

Like other biological macromolecules such as polysaccharides and nucleic acids, proteins are vital to the metabolism of all living organisms. Proteins play an essential role in the tissue of live animals and carry out various functions, such as actin and myosin, which are contractile proteins essential for movement and locomotion.

Proteins consist of one or more chains of amino acids, and they differ from one another primarily in the sequence of amino acids. Proteins can be hydrolyzed into polypeptides or amino acids by proteases. Amino acids are essential nutrients, and some are supplemented in foods in both natural and synthetic forms (Ikeda, 2003). Quantitative and qualitative analyses of amino acids are important to the food industry in general, but are especially critical for quality assurance in the amino acid industry.

However, for protein molecules their function depends on the specific three-dimensional structures that are easily altered by physical, chemical, and biological factors like heat,

presence of organic solvents, and microorganisms. Functional properties of proteins are, therefore, also an important element of protein analysis (Hall, 1996). Methods commonly used to analyze protein structures and functions included those based on site-directed mutagenesis, nuclear magnetic resonance, X-ray crystal diffraction, and mass spectrometry (MS) (Cavanagh *et al.*, 2010; Ladd and Palmer, 2003; Whitford, 2005; Zhang and Smith, 1993). As such, proteins are often purified using a wide range of techniques such as ultracentrifugation, precipitation, chromatography, and electrophoresis (Janson, 2012).

Nutritive value of a protein also needs to be evaluated apart from amino acid composition, protein content, and protein structure and function. The most commonly evaluated parameters are the amino acid score (AAS), net protein utilization (NPU), true digestibility (TD), and biological value (BV) (Owusu-Apenten, 2002).

Lipids

Lipids are essential to living organisms because they contribute to vital metabolic processes in cells. Fats such as butter and lard are derived from animal products such as milk and meat, whereas oils such as soybean oil, peanut oil, and olive oil are derived from plants. Lipids can be categorized into two classes: saturated and unsaturated, which are dependent on the fatty acid backbone of the triacylglyceride. Melting points of saturated fatty acids are higher than those of unsaturated fatty acids. Therefore, most animal fats with a high content of saturated fatty acids are in the solid form at room temperature, whereas lipids from plants such as olive oil are liquid on account of the higher content of unsaturated fatty acids.

The taste, flavor, and nutritional value of food, as well as the health of humans, are affected by the variety and quantity of the lipids, because of the potentially toxic oxidation byproducts of lipids (Kubow, 1992). In addition, some mono- and polyunsaturated fatty acids can help reduce the risk of human chronic diseases beyond their basic nutritional functions (Jew *et al.*, 2009). An accurate and precise analysis of total and individual lipids is essential for the development of safe and high-quality foods and functional foods.

Minerals

What makes minerals different from organic nutrients is that minerals cannot be synthesized or decomposed in a biological system like the human body. According to the requirement of minerals by living organisms, they can be categorized into macrominerals such as calcium, potassium, phosphorus, and trace minerals like iron, iodine, and zinc (Faller *et al.*, 2004). Although the requirement of trace minerals is low, they are very important for metabolism. Minerals are obtained through food, and those necessary in maintaining healthy metabolism are called essential microelements. In some cases, fortification is allowed in the diet. Mineral analysis is of great significance but highly challenging for evaluating the nutritional value, potential toxicity, and food safety, especially for the trace elements in food. Modern instrumentation plays an important role in obtaining accurate, precise, and sensitive results in mineral analysis.

Vitamins

A vitamin, including fat-soluble and water-soluble vitamins, is defined as an organic compound present in minute amounts in natural foodstuffs that are required by humans or any other organisms as a vital nutrient at low concentrations (McDowell, 2008). Insufficient levels of vitamins result in hypovitaminosis or avitaminosis.

Many vitamins are lost or decomposed during food processing. Monitoring the stability and reducing the loss of vitamins in raw and prepared foods or food supplements thus requires accurate and sensitive analytical methods. Such methods are also important for assessing dietary adequacy.

Dietary Fibers

Dietary fibers, including soluble and insoluble ones, have special physiological functions such as protecting against colon cancer, lowering the cholesterol absorbed, reducing the risk of obesity, and cardiovascular diseases. Research has shown that dietary fibers changed the microbial contents of the gastrointestinal tract in favor of the growth of beneficial bacteria against the pathogenic ones (Eastwood and Kritchevsky, 2005).

Physicochemical and Biological Properties

Energy

Food energy is defined as the energy released from carbohydrates, fats, proteins, and other organic compounds. When the three major calorigenic nutrients (carbohydrates, fats, and proteins) in a food are burnt entirely with sufficient amounts of oxygen, it releases energy or food calories that are expressed in kilojoules (kJ) or kilocalories (kcal). Food energy is usually measured by a bomb calorimeter based on the heat of combustion (Insel *et al.*, 2012).

Energy released by a particular food is a critical parameter in nutrition. Several chronic diseases such as obesity, diabetes, and cardiovascular disease have been considered to be caused by excess energy intake. All food manufacturers are now required to label the energy of their products to help consumers control their energy intake. Fats have the greatest amount of food energy per mass, up to 9 kcal g^{-1}. Most of the carbohydrates and proteins have approximately 4 kcal g^{-1}, whereas fibers have less due to its low digestibility and absorbance in human bodies (Insel *et al.*, 2012). Restricting long-term consumption of high-energy foods rich in fats and sugar can reduce the incidence of obesity and other diseases.

pH and Acidity

There are two indicators of food flavor and quality: pH and acidity. Most common organic acids in foods are just partially ionized. In food processing, optimization of flavor and taste, and improvement of formulations are often done by controlling the pH and the acidity, which are also important for effectively inhibiting the activities of enzymes and the growth of microorganisms, ultimately improving the food quality and

prolonging the shelf-life of the product (Brown, 2010; Vaclavik and Christian, 2003).

Texture

The texture of the food is its physical and chemical interaction in the mouth and can directly correlate to food rheology. Food texture encompasses hardness, smoothness, thickness, and other mouth-feel characteristics (Lawless and Heymann, 2010). Food is constantly evaluated, from the initial impression when the product touches the palate, until the aftertaste. Physical properties that contribute to the texture of a food are now widely used to represent the state and taste of that respective food. The collective expression of food texture through such properties at present is measured using mechanics and by visual and auditory methods.

Food texture has been used to: (1) explain food structural characteristics; (2) explain changes of physical properties of a food during processing and cooking processes; (3) improve food quality and unique characteristics; (4) explore the relationship between sensory analysis and the instrumental measurement(s).

Rheological Properties

Like texture, rheological properties are also one of the significant assessment criteria of food quality. The rheological properties of food, such as consistency, viscosity, and elasticity, are very important factors and are used to evaluate the stability of a food during processing, and the shelf-life during storage (Herh *et al.*, 2000). A proper design of food formulation can therefore improve the shelf-life and sensory characteristics by measuring the rheological properties.

Foods can be classified into solid, liquid, emulsion, and gel according to their rheological state (Rao, 2007). However, due to the complex structural features of different food components, a food often appears to be a mixture of solid and fluid with varying properties. Rheological properties of a complex food matrix are obtained through disciplinary approaches, using theoretical and experimental information to gain a better understanding of various properties of food materials.

Color

Whether or not people decide to buy a food depends, to a large extent, on the appearance of the product, among which the most important factor is color, and seems to have an innate allure that gives people the first impression and the greatest influence on our judgment (Potter and Hotchkiss, 1998). For consumers, the most intuitive feeling for products is the color.

Improving and maintaining color stability is one of the most important practices in food processing. Colorants are often added into products in the food industry to enhance the appeal of foods. Natural pigments are normally not required to be certified before they are added to foods because they are generally considered to be safe (Ronzio, 2003). Naturally derived pigments are typically more expensive than certified synthetic colorants and may add unintended flavors to foods. However, certified colorants are synthetically produced and are used widely because they are less expensive, as well as they impart an intense, uniform color, and blend more easily in food to create a variety of hues (Potter and Hotchkiss, 1998). Under these circumstances, the levels of colorants added should be monitored to ensure that appropriate regulatory guidance is complied with.

Flavors

People enjoy the products with good flavor which can, in turn, affect the digestion and absorption of nutrients. Flavor is just the sensory impression of a food mainly caused by the chemical senses. In general, the chemical senses are divided into two types: taste and smell. Sour, sweet, bitter, piquant, salty, umami, and metallic are the seven basic tastes, whereas smell is only limited to fragrance and stink (Jeleń, 2011; John, 1995).

A flavor is determined by a mixture of several compounds in most foods. If one or several compounds represent the characteristic flavor of a particular food, these are considered as the characteristic or key compound(s). These substances have the properties of poor stability, small quantity, and vulnerability (Philippe *et al.*, 2003).

Flavoring can be practices that are used to prevent undesirable flavors produced during treatment, storage, and processing of food, or to create desired flavors for specific products such as candies and other snacks. Natural or artificial flavorants alter the taste of the food itself. Most commercial flavorants used in the food industry are chemically synthesized rather than extracted from native materials, as artificial flavorants are much less expensive and more available (Chandrashekar *et al.*, 2006). As a result, in food industries, flavor analysis must be performed to ensure food quality and safety.

Sampling and Sample Preparation

Sampling

Food analysis always starts with sampling which is the process of taking a representative fraction from a large collection of a particular product or item, for example, a small quantity from a full production batch.

Before sampling, the objective and target analytes or properties of a food must be well established and understood, so an appropriate sampling method is determined for reliable results. There are two methods of sampling: random sampling and representative sampling. Opportunities for drawing any individual sample from the population in the process at random must be equal (Rana, 2008).

Sample Preparation

To eliminate the interference of other components, and increase the concentration of the target components, samples are often pretreated before analysis. Sample preparation also increases uniformity thus leading to better extraction

efficiency. Below are some commonly used sample preparation methods:

Methods for removal of organic compounds

These methods are mainly used for the determination of inorganic elements. The inorganic elements of the food often bind tightly with organic compounds such as proteins. Therefore, organic compounds are removed to reduce/eliminate potential interference. The details are discussed in the Section Ash Content Analysis.

Solvent extraction

Solvent extraction is commonly used to remove unwanted components by taking the advantage of significantly different solubilities between the analytes and interfering compounds. Solvent extraction methods include lixiviation, supercritical fluid extraction (SFE), ultrasonic extraction, microwave-assisted extraction, and solid phase extraction.

Chromatography

Although modern chromatography has been largely instrumentalized and automated for analytical purposes, some manual are still widely used in sample cleanup and preparation, and more details are discussed in the Section Chromatography.

Grinding

For sample preparation before analysis, grinding is important. It reduces the particle size of solids and semisolids, and improves the uniformity and increases extraction efficiency of the sample. Various mills are available for reducing the particle size to achieve sample homogenization.

Other methods

Concentration: Concentration reduces sample size and enriches the target components to make the samples easier to be analyzed. Concentration of liquid samples is done by evaporation under vacuum or atmospheric pressure.

Distillation: Distillation, including air distillation, reduced pressure distillation, and steam distillation, separates analytes from the interfering components based on their different boiling points. Usually, no reagents are needed during this process.

Precipitation: The appropriate chemical agents, such as basic copper sulfate, isolate the target components or interfering compounds by settling them out of solution. Filtration or centrifugation is carried out to either recover the precipitate or the supernatant for analysis.

Masking: A masking agent is added to bind selectively to an interfering component; therefore, only the analytes are available for extraction or further analysis.

Sulfonation and saponification: These two methods are used to remove lipids from samples.

Sample Preservation

Ideally, all samples should be analyzed upon arrival at the laboratory. However, more often than not, samples are stored before analysis. In the latter case, samples must be kept under appropriate conditions. Light, oxygen, temperature, and moisture are the major factors that cause deterioration of the sample and the analytes. Exposure to light and oxygen (air) leads to oxidation including photodegradation of compounds, for example, riboflavin and carotenoids. Temperature and moisture affect microbial growth and enzyme activity in the samples. Preservatives and antioxidants can be added into the samples on the condition that they will not affect the analysis results. Freeze-drying and ultralow temperature are good preservation techniques for samples that cannot be analyzed timely. Proper preservation methods must be chosen based on the probability of contamination, storage time, and the target analytes.

Enzyme inactivation

Raw food material often contains endogenous enzymes, which may decompose the primary elements, that is, proteins, thereby leading to interference upon analysis. Therefore, these enzymes must be eliminated or controlled. In general, thermal treatment is the most common method to inactivate enzymes. Sometimes, samples are frozen during storage to limit enzyme activities. However, activities of some enzymes are more effectively regulated by changing the ionic strength or pH.

Lipid oxidation protection

Unsaturated lipids are protected through storage in vacuum or under nitrogen, as they are sensitive to oxidative degradation. Lipids may be stabilized by antioxidants that could be used upon analysis (Kadoya, 1991). Low-temperature storage is suitable for protecting most foods. Light-initiated photooxidation of unsaturated lipids are avoided by being stored in the dark. Containers for lipid samples should be free of any transition metals as these ions are catalysts for lipid peroxidation.

Microbial growth inhibition

Microbial contamination can occur during sampling and even processing for analysis; therefore, efforts must be made to avoid exposure to microorganisms at each step between sampling and analysis. Freezing, drying, and chemical preservatives are effective controls and often a combination of these are used (Nielsen, 2010b).

General Analysis Methods

Moisture Analysis and Water Activity Measurement

Oven drying: The moisture content of the samples is calculated by the loss of weight. The loss of moisture from a sample is a function of time and temperature in the process of analysis. Sometimes, the components in the food may be decomposed at a higher temperature; while the volatile constituents, such as acids, alcohols, and other flavor compounds, may also be lost. Moisture content can be calculated using oven drying procedures, such as the following (Nielsen, 2010b):

$$\%\ \text{Moisture content (wt/wt)} = \frac{\text{wt } H_2O \text{ in sample}}{\text{wt of wet sample}} \times 100 \quad [1]$$

$$\%\ \text{Moisture content (wt/wt)} = \frac{\text{wt of wet sample} - \text{wt of dry sample}}{\text{wt of wet sample}} \times 100 \quad [2]$$

Oven-drying methods generally include air, vacuum, microwave, and infrared drying. Drying under reduced pressure leads to more efficient and complete removal of water and volatiles, less decomposition, and reduced drying time. Microwave drying, in which the samples must be uniform, centrally located and evenly distributed in order to prevent uneven heating of the sample, has the advantages of rapidity and accuracy. Infrared drying techniques are more suited for qualitative online processes, because of the rapidity of analysis: however it has not yet been approved by Association of Official Analytical Chemists.

Distillation: The principles have been discussed in the Section Sample Preparation. Distillation causes less thermal decomposition of some foods compared with oven drying at high temperatures.

The Karl Fischer Method: The principle of the Karl Fischer method is schematically based on the following oxidoreduction reaction:

$$SO_2 + I_2 + 2H_2O \rightleftarrows 2I^- + 4H^+ + SO_4^- \quad [3]$$

Others: Infrared (IR) spectroscopy (see Section Infrared spectroscopy) has been successfully used in the laboratory and in online applications. For water, the –OH stretching at 1400–1450 nm and 1920–1950 nm (near-IR (NIR) bands) are characteristic (Ozaki *et al.*, 2006; Workman and Weyer, 2007). Dielectric method is used to determine the moisture content by the electrical properties of water. Hydrometry is still widely used for routine analysis of moisture (or solids) content of numerous products. Refractometry is used commonly to measure the content of moisture in liquid sugar products with the characteristics of convenience, rapidity, and surprising accuracy. It is also used online to monitor the Brix of products in real time.

Water activity: Water activity (a_w) is one of the most important physicochemical properties for predicting the growth and the survival of microorganism in foods. In addition, it significantly affects lipid oxidation, endogenous enzyme activity, and nonenzymatic browning reactions. a_w is a thermodynamic concept, defined as the vapor pressure of a liquid divided by that of pure water at a given temperature. More details are in the reference (Barbosa-Cánovas *et al.*, 2008).

There are various techniques to measure a_w, among which are the portable water activity meters. As shown in **Figure 1**, the developed portable water activity meters that are widely used in the food industry can yield accurate measurements in less than 5 min, where the reading is directly displayed on the screen of the instrument.

Figure 1 AquaLab 4TEV water activity meter.

Ash Content Analysis

Ash is the inorganic residue after all organic components of a food sample are burnt. Two major types of ash analysis are used: dry ashing, which is primarily used for specific mineral analyses and wet ashing, a method based on completely oxidizing organic compounds using chemical agents. Before ashing, drying and degreasing must be done, especially for high-fat products. The ash content of foods is expressed on either a wet or a dry weight basis.

Dry ashing refers to the method of burning organic substances completely in the presence of oxygen by using a muffle furnace capable of maintaining temperatures of 500–600 °C, at which water and volatiles are vaporized (Sharma, 2006). Most minerals are converted into oxides, sulfates, and other inorganics. This method requires no reagents, as well as, little attention during combustion, but the drawback is that it is time consuming and losses may occur for some volatile elements and mineral components that may interact with crucibles. Strong acids or other oxidizing agents, or their combinations are used in wet ashing. During the procedure of wet ashing, minerals are solubilized in a solution, and because it is done at an ambient temperature, no loss occurs from volatilization (Aras *et al.*, 2006). This is a faster method because of the quick oxidation time.

Recently, a novel method called microwave ashing has been developed (Nollet and Toldrá, 2012). Assisted by a microwave instrument, both dry ashing and wet ashing can be done. The microwave-assisted method is mainly used for accelerating the digestion of samples.

Carbohydrate Analysis

Total carbohydrates

Carbohydrates can be destroyed by the addition of a strong acid and/or high temperature, where various furan derivatives are produced. The furan derivatives react with phenols to produce reaction products that can be conveniently measured by a spectrophotometer. This method, namely, phenol-sulfuric acid method, is rapid, simple, sensitive, accurate, and specific for carbohydrates, and widely applied (Chandrasekaran, 2012). The reagents are also readily available, inexpensive, and stable.

Total reducing sugar

Reducing sugars naturally existing in foods or released by enzymes are determined by the dinitrosalicylic acid method. In this reaction, 3,5-dinitrosalicylate is changed to the reddish monoamine derivative, which can be measured by a spectrophotometer. This reaction is not stoichiometric and must be determined with a standard curve of D-glucose (Robyt, 1998). Another often used is the Somogyi–Nelson method. It is also used for the determination of oligo- and polysaccharides (Chandrasekaran, 2012).

Mono- and oligosaccharides

Mono- and oligosaccharides such as D-psicose, difructose anhydride III and oligofructose are commonly analyzed using high-performance liquid chromatography (HPLC) (Zhang *et al.*, 2009; Zhao *et al.*, 2011, Hocine *et al.*, 2000). HPLC identifies individual sugars with specific retention times and gives quantitative results with peak integration. It is a rapid, precise, and accurate method for a wide range of samples.

Ionic-exchange, normal-phase and reversed-phase chromatography are widely used for the analysis of sugars in different foods such as honey, beverage, cakes, and ice creams. In anion-exchange chromatography, the general elution sequence is alditols, monosaccharides, disaccharides, and higher oligosaccharides (Nielsen, 2010b). The elution order is reversed in cation-exchange chromatography (Rassi, 1994). In normal-phase chromatography, the stationary phase is the silica gel derivatized with amino groups, and acetonitrile water (50–85% acetonitrile) is a commonly used mobile phase. The elution order is monosaccharides and sugar alcohols, disaccharides, and higher oligosaccharides. In the reversed-phase chromatography, the hydrophobic stationary phase is silica gel with alkyl chains or phenyl group, such as a C18 column or phenyl column. It is used for the analysis of mono-, di-, and trisaccharides (Nielsen, 2010b).

Thin-layer chromatography (TLC) has been used for the analysis of mono- and oligosaccharides. Although it provides both quantitative and qualitative information of the sugars, TLC is not as sensitive and accurate as HPLC. More information in detail is provided in the reference (Sherma and Fried, 2003).

Starch, food gum, and dietary fiber

The starch content is determined by the amount of D-glucose released from the hydrolysis reaction by purified enzymes specific for starch. The enzymes for starch hydrolysis must be purified to prevent the release of D-glucose by other enzymes. For example, cellulose can be converted into D-glucose by cellulases. The presence of nonstarch specific enzymes can cause an overestimation of the total starch content.

The degree of gelatinization of starch is measured by a combination of pullulanase and β-amylase, which is particularly sensitive and only able to act on gelatinized or pasted starch. The determination of the content of food gum, like pectin, is discussed in detail in the reference (Nielsen, 2010b). Dietary fiber is usually determined gravimetrically. The Prosky method is the principal procedure, which measures both soluble and insoluble fiber. The Englyst-Cummings method is used for the chemical measurement of dietary fiber (Shils, 2006).

Protein Analysis

Kjeldahl method: In the Kjeldahl procedure, after digestion in concentrated sulfuric acid, the total organic nitrogen is converted to ammonium sulfate. Ammonia is formed and distilled into boric acid solution under alkaline conditions. The borate anions formed are titrated with standardized hydrochloric acid, by which is calculated the content of nitrogen representing the amount of crude protein in the sample. Most proteins contain 16% of nitrogen, thus the conversion factor is 6.25. However, the nitrogen from nonprotein additives or contaminants in the food, such as melamine in milk, is also measured.

Biuret method: Under alkaline conditions, peptide bonds react with cupric ions to produce a violet-purplish color, the intensity of which at 540 nm is correlated to the protein content of the sample (Owusu-Apenten, 2002). This method is quick and simple with little interference from nonpeptide or nonprotein sources.

Lowry method: The Lowry method is developed based on the biuret method. Proteins react with Folin–Ciocalteu phenol reagent to produce a blue conjugate at 750 nm. The intensity of color is proportional to the protein content of the sample (Owusu-Apenten, 2002). Although this method is very sensitive, it is interfered by sucrose and lipids.

Ultraviolet 280 nm Absorption Method: Proteins, at 280 nm, show strong absorption primarily for tryptophan and tyrosine residues. This technique is mainly applied in a purified protein system, because absorbance will be falsely increased if particulates or other substance like nucleic acids are in the solution (Scopes, 1994). This method is noninvasive; thus samples can be used for other analyses after protein determination.

Other methods: In addition to the aforementioned methods, the Dumas, IR spectroscopy, bicinchoninic acid, anionic dye-binding, Bradford dye-binding, Ninhydrin, and immunological methods are some other techniques commonly used for protein analysis (Nielsen, 2010b; Owusu-Apenten, 2002; Ozaki *et al.*, 2006). Choosing an appropriate method depends on the properties of proteins present in the samples as well as the characteristics of analytical approaches.

The nutritional value of a protein is determined by the amino acid composition and the digestibility of that protein. The most common parameters for protein quality are the AAS, BV, TD, and NPU. The procedure for calculation is further elaborated in the reference Owusu-Apenten (2002).

Lipid Analysis

Solvent extraction method: The total lipid content of a food is commonly determined by its organic solvent extract. The choice of solvents is highly critical for total fat analysis. The most commonly used solvents are ethyl ether and petroleum ether, but pentane and hexane are used for extracting oil from soybeans. In addition, lipids in food may be conjugated with proteins and polysaccharide; thus, a successful extraction requires that the lipids be freed by alkaline or acid hydrolysis and then extracted into the organic solvents. The Goldfish method is commonly used as a continuous solvent extraction approach. In this procedure, solvent from a boiling flask continuously flows over the sample. Fat content is measured by the weight of fat loss of the sample. Soxhlet method is a semicontinuous solvent extraction approach. In this procedure, the sample is soaked completely for 5–10 min in a solvent and then siphoned back into the boiling flask. A commercial Soxhlet apparatus is shown in **Figure 2**. The Mojonnier test is an example of the discontinuous solvent extraction method. SFE (Anklam *et al.*, 1998) is a relatively

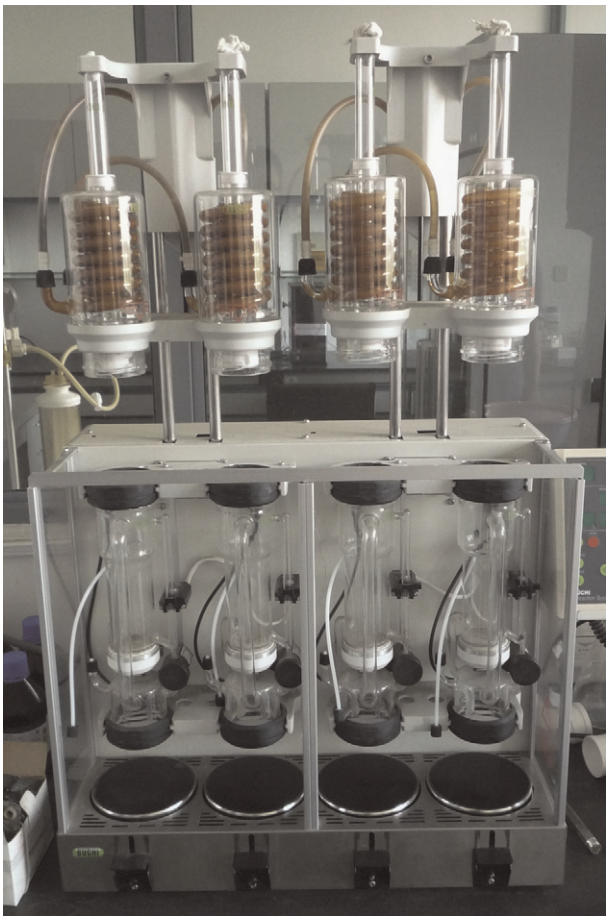

Figure 2 Soxhlet extraction apparatus.

new solvent-free technology developed to replace or reduce the use of toxic organic solvents.

Nonsolvent wet extraction methods: The Babcock method and Gerber method are commonly used for milk fat analysis. In these procedures, carbohydrate and protein are removed by centrifugation after addition of H_2SO_4. Milk fat is separated and measured volumetrically, and the result is expressed as a percentage of fat by weight.

Gas chromatography (GC): GC is the most sensitive and accurate method for fat analysis. A triglyceride, triundecanoin (C11:0), is added as an internal standard. More information is in the Section Gas chromatography.

Other methods: Details of some other methods such as IR, specific gravity, nuclear magnetic resonance, and ultrasonic method can be found in the reference (McDonald and Mossoba, 1997).

In addition to the total lipid content, physicochemical properties of the lipids in a foodstuff, such as stability and safety of fats, are also important to be characterized. Refractive index, melting point, smoke point, flash point, fire point, and cloud point are commonly measured. Degree of unsaturation of fats or oils is indexed by the iodine value. Higher iodine value is indicative of a higher degree of unsaturation. Saponification is an alkaline hydrolysis process by which neutral fats (triglycerides) break into glycerol and fatty acids. Saponification value is an index of the mean molecular weight of the triacylglycerides in the samples. The amount of fatty acids hydrolyzed from triacylglycerides is reflected by the acid value. Peroxide value tests the peroxide products after lipid oxidation. The thiobarbituric acid test measures the secondary products of lipid oxidation, primarily malondialdehyde. Details on these and other indexes also can be found in the reference (Nielsen, 2010b).

Mineral Analysis

Atomic absorption spectroscopy is the most commonly used method for mineral analysis, and it will be discussed in detail in the Section Atomic absorption and emission spectroscopy. Inductively coupled plasma MS (ICP-MS) is introduced in the Section Raman spectroscopy. Only traditional titration methods are briefly introduced here.

Gravimetric analysis: This method is only for insoluble minerals. The mineral content of the sample is weighed after proper precipitation, washing, and drying. It is not suitable for the determination of trace elements.

Ethylenediamine tetraacetic acid complexometric titration: Ethylenediamine tetraacetic acid (EDTA) forms stable 1:1 complexes with numerous mineral ions except alkali metals, and this principle has been the basis of the widely used complexometric titration. The endpoint of a complexometric EDTA titration is the color change from pink to blue using either Calmagite or Eriochrome black T as the indicator (Nielsen, 2010a).

Precipitation titration: It is well suited for any foods that may be high in chlorides (Dieter and Multon, 1997). However, it ultimately has few applications in the analysis of food.

Colorimetric methods, redox reaction, and ion-selective electrodes may also be used in mineral analysis (Nielsen, 2010b). These procedures generally require only inexpensive chemicals and equipment readily available in an analytical laboratory.

Vitamin Analysis

HPLC, owing to its simplicity, and good accuracy and precision, is a preferred method for vitamin analyses (Leenheer and Lambert, 2002; Nollet, 2012). HPLC is suitable for most lipid-soluble and water-soluble vitamins such as vitamins A, C, D, and E and the B vitamins, respectively. Liquid chromatography (LC) in combination with MS is particularly useful for vitamin analysis. Detection by LC–MS leads to increased sensitivity as well as unequivocal identification and characterization of vitamins. In addition to the UV/Vis or diode array detector, fluorescence spectroscopy detector is also used in HPLC, especially for B vitamins such as thiamin (vitamin B_1).

Physicochemical Analysis

pH and Acidity

In food analysis, pH is different from titratable acidity, but there is a close relationship between them. Titratable acidity indicates the total acidity contained within a food, whereas pH only means the free H_3O^+ concentration. Total acids, which give

more impact on flavor, are determined by exhaustive titration of the intrinsic acids with a standard base. The growth of microorganisms is more dependent on pH than total acids. In nature, the value of pH can span from 1 to 14 orders of magnitude.

pH is usually determined using a pH meter or pH indicator. Titratable acidity is determined by neutralizing the bases present in the sample using a standard acid. When the color of a pH-sensitive dye changes suddenly, the titration reaches the endpoint. The endpoint of the target pH is identified by the pH meter. The advantage of the potentiometric method is that the precise equivalence point is identified. The titration of acids or bases is also determined by the conductometric method, which is also applied for the determination of halides, sulfides, and mercaptans (Paré and Bélanger, 1997).

Thermal Analysis

A set of physical properties of foodstuff and food products, such as texture and storage stability, can be analyzed by thermal analysis, which provides information on the structures and qualities of the material. Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) (Nielsen, 2010b; Pomeranz and Meloan, 2002) are two typical methods in thermal analysis.

Thermogravimetric analysis: TGA measures the thermal or oxidative stability of the components of the samples. When samples are heated from room temperature to 1000 °C or higher, even small weight changes due to the decomposition of components are detected by TGA instruments (**Figure 3**). However, it does not identify the gaseous compounds evolved from the sample.

Differential scanning calorimetry: DSC can measure structures such as amorphous, crystalline, or semicrystalline components of food, based on the fact that structural changes occur as a result of heat absorption or release (**Figure 4**). It is perhaps one of the most useful of the thermal techniques for identifying the structures and their changing characters.

Texture and Rheological Analysis

There are no better ways to quantify the sensory properties of a product in the mouth than by measuring the physical properties related to the sensory texture of foods. These properties are determined by rheological methods and texture analysis. Instrumental and physiological methods are used to determine a food's quality and structural characteristics, thus providing a more accurate description of a product, which subsequently can help control the quality and structure of food.

Viscosity and other rheological properties of materials are determined by rheometers. Viscosity for fluids is the most important parameter, providing rapid and fundamental information. Some common foods exhibit ideal Newtonian flow: however, the majority of fluid foods exhibit pseudoplasticity. If the viscosity of a material increases in response to increased rate of shear strain, such as cornstarch slurry, the material is called a dilatant (Rao, 2007; Steffe, 1996). The rheological properties of solid foods are determined by extending, compressing, or twisting the samples. The process, by which samples are significantly deformed, strained, damaged, or possibly fractured by mechanical forces, simulates the process of chewing resulting in the change of food texture in the mouth (Bourne, 2002).

Texture profile analysis (TPA) is an important technique using the texture analyzer. Numerous sensory parameters, including hardness, springiness, and cohesiveness, are determined by the TPA test (Bourne, 2002). For example, sample hardness has been strongly related to the highest force fracturing the sample. **Figures 5** and **6** show rheometer and texture analyzer, respectively.

Color Analysis

The concept of color is defined as the sensation that can be interpreted by our brain. In chromatology, the Munsell system is probably the best known and the most widely used one (John, 1995; Lawless and Heymann, 2010). A food color can be mathematically represented by the International

Figure 3 TGA Spirit Drinks Trade Act (SDTA) 815.

Figure 4 DSC Q2000.

Figure 5 ARES-G2 rheometer.

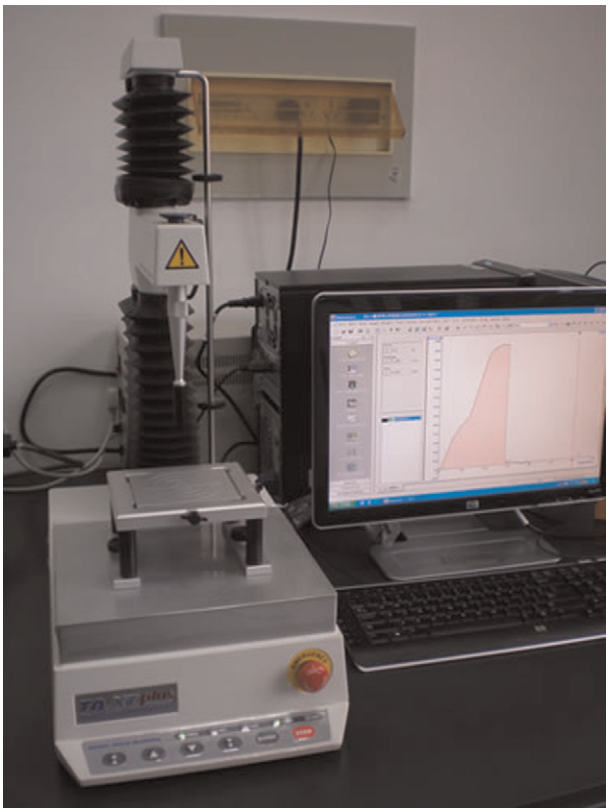

Figure 6 TA XT plus texture analyzer.

Commission on Illumination tristimulus values, although such values are difficult to be directly related to the observed color.

The colorimeters are commercially available today. They are portable, online for process control, and specialized for specific commodities. However, quantitative analysis of artificial and natural colorants has been a great challenge in food processing. The properties of colorants and their derivatives and the interaction between colorants and other components make the qualitative and quantitative analysis very complex. Sometimes, especially in thermal processing, colorants are difficult to be extracted. In addition, they are also sensitive to oxygen, heat, light, and metal ions. The common methods for colorant analysis are stand-alone UV–Visible spectrophotometry and HPLC using a UV–vis detector. More details are discussed in MacDougall (2002).

Sensory Analysis

Sensory analysis combines experimental methods and statistical analysis for the purpose of evaluating food products using human senses (sight, taste, smell, touch, and hearing). It greatly depends on the sensation of the assessors, which is related to the psychological factors at that time (Carpenter *et al.*, 2000). It is possible to make inferences about the quality of products under test by applying statistical methods to the results.

The sensory testing environment is vital to the perception of analysts, because they more or less cause specific physiological sensations/ characteristics. According to standardized procedures, sensory specialists need to be very careful in experimental design, selection of protocols, and preparation of samples before testing. The visual appearance, such as size, shape, the quantity, and even the container of the samples should be decided carefully. There are many methods for designing experiments; the experimental design is divided into two basic structures, namely treatment structure and design structure (Lawless and Heymann, 2010).

In the process of testing, people's sensory opinions of food is collected and described. Normally, the number of experts should not be less than five. Further details regarding sensory analysis can be found in these references (Carpenter *et al.*, 2000; Chambers, 1996; Lawless and Heymann, 2010).

Biological Analysis

Enzyme Application

Enzymatic analysis involves the measurement of the activity of specific added commercial enzymes and/or endogenous enzymes, which can be used to indicate the quality of food. The enzyme reactions require less reaction time and cost less in contrast to complicated chromatographic separation techniques.

There are several uses of enzymes in food science and processing. For instance, peroxidase and lipoxygenase, two endogenous enzymes found in vegetable products, are used as a measure of adequacy of blanching (Fennema, 1996). In addition, glucose content in the presence of other reducing sugars can be determined by the combination of the glucose oxidase (GOX) and catalase in a food system (Aehle, 2007). It

is a useful tool in determining the amount of glucose because of the GOX specificity for glucose.

Immunoassays

Immunoassays are widely used for food toxins such as pesticide residues, mycotoxins, process-induced toxins and drugs, identification of bacteria and viruses, and detection of allergens in food, which attribute to their high specificity, sensitivity and simplicity (Tothill, 2003).

Enzyme-linked immunosorbent assay (ELISA) is a common immune analytical technique based on the high and specific affinity binding of particular target antigens with antibodies. Horseradish peroxidase and alkaline phosphatase are most commonly used in immunoassays, because these enzymes can convert colorless substrates to colored soluble products in order to generate the detectable signals for the assay. Western blot is another common method that combines two techniques: polyacrylamide gel electrophoresis (PAGE) and immunoassay.

Food Contaminants and Residues Analysis

Microbiological Analysis

Food products may be exposed to potential risks of microbial contamination during the process of production, transportation, and at the point of sale.

Traditional methods for the detection and identification of microorganisms in food largely depend on the culture method. A general strategy to detect specific microorganisms is to identify first the target organism and determine the nutritional requirements for the optimal growth of the target microorganism. Optimum incubation conditions including temperature, time, and atmosphere are then established (Lund and Baird-Parker, 2000). Finally, assessment of the performance against an established method using contaminated foodstuff is carried out.

In recent years, with the rapid advancement in molecular biology and microelectronics technology, faster, more accurate and specific testing methods have emerged as novel alternative tools for the identification of microorganisms. The following is a few examples of the new technologies:

Electrical impedance method: During the growth of bacteria, the inert macromolecules such as carbohydrates, proteins, and lipids in the culture medium will degrade into electrically active small molecules such as lactate and acetate, which can increase the conductivity of the medium, causing changes in the impedance of the medium. Detection of such changes can be used as an indicator of the growth and characteristics of the corresponding bacteria in the medium (Harrigan, 1998). It has been used for the detection of the total number of bacteria, fungi, yeast, *Escherichia coli*, *Salmonella*, and *Staphylococcus aureus*.

Nucleic acid probe technology: The nucleic acid probe, marked with specific deoxyribonucleic acid (DNA) fragments, is used to hybridize with target DNA, specifically. The probe can be labeled using either radioactive or nonradioactive labeling. The nonradioactive labels can be biotin, digoxigenin, fluorescence labeling, and immunolabeling (Harrigan, 1998; Jay, 1996). This method has been successfully used in the detection of *Salmonella* and *Listeria*.

Polymerase chain reaction technology: It can detect *Salmonella*, *E. coli* O157, and *Listeria monocytogenes* (Patel, 1994): Although it requires special equipment, polymerase chain reaction is a novel technology that has the advantage of being rapid, sensitive, accurate, and is the promising method for detecting microorganisms in the future.

Enzyme-linked immunosorbent assay: The principal of ELISA, in detail, is given in the Section Immunoassays. The amount of aflatoxin is usually measured by this technology.

Pesticide and Veterinary Drug Residue Analysis

Pesticides in food can be herbicides, insecticides, fungicides, acaricides, molluscides, nematicides, pheromones, plant growth regulators, repellents, and rodenticides. Results of pesticide residue analyses are influenced by several factors including food components, the physical and chemical properties of the pesticides, and the interaction between the food matrix and the pesticide molecules. A wide range of analytical methods has been used in pesticide analysis. The enzyme inhibition assays and immunoassays are commonly used for the measurement of pesticides. Testing kits are also commercially available. Pesticides with enzyme-inhibitory activities will develop color; thus their residues can be quickly detected using these methods. Chromatographic techniques, including TLC, GC, HPLC, GC–MS, and LC–MS, are widely used in the analysis of pesticides. Details of these techniques are discussed in Sections Mass Spectrometry and Chromatography.

Veterinary drugs are used to reduce the risk of disease outbreak in the animal population. In addition, they are used to promote animal growth and increase feed conversion in animals (Picó, 2008). A wide variety of analytical methods have been developed and optimized for the analysis of the drugs including antibiotics. Microbial growth inhibition assay is usually used for quantitative measurement of the veterinary drugs. If the drugs are present in samples, the microbial growth is inhibited. Enzyme substrate assays, immunoassays, HPLC, LC–MS, and LC–MS/MS have all been applied for the analysis of feed additives and veterinary drugs in foods.

Other Chemical or Biological Contaminants

Genetically modified organisms: The safety of genetically modified foods (GMFs) is a concern not only to the general public but also to the food industry and government regulatory agents. Currently, soybeans, corn, and canola have been implicated in genetically modified organisms (GMO) products. In addition to these common GMO field crops that are modified for pesticide and herbicide-tolerance, other GMO foods from both flora and fauna have been developed for improved or enhanced quality and nutritional value (James, 2001). For example, genetically modified fruits have better taste and potentially a longer/ extended shelf-life. Another example is 'golden rice,' which has been engineered to produce vitamin A precursor (Paine *et al.*, 2005). In general, there are two methods for detecting GMO. Immunoassays, for detecting the proteins of GMO, are highly specific methods because they are based on the use of antibodies. However, detection of the transgenic

DNA itself, such as the promoter sequence is another effective method for the identification of GMFs (Nielsen, 2010b).

Melamine: Melamine was added illegally to milk products and animal feed to falsify the protein content, which caused illness and death of infants. LC–MS is commonly used for melamine analysis. However, several rapid and less expensive methods such as near- and mid-IR technologies and immunoassays have also been developed (Picó, 2012; Hui *et al.*, 2006; Vail *et al.*, 2007).

Residues of Packaging Materials: The health risks of novel plastic food packing materials or the plasticizers/additives thereof have become an increasingly serious food safety issue in recent years (Robertson, 2012). Chemicals such as bisphenol A and 4-methylbenzophenone are used in plastics, but their residues can migrate into food. To ensure food safety, residue levels of packing material in food are highly regulated and monitored using GC–MS, GC–MS/MS, LC–MS, and LC–MS/MS. Other analytical methods include uses of commercially available immune-affinity columns and ELISA kits.

Modern Instrumental Analysis

Spectroscopy

Ultraviolet and visible spectroscopy

Ultraviolet and visible spectroscopy (UV–vis) is one of the most commonly encountered techniques in food analysis. The wavelength of UV light ranges from 200 to 350 nm, and that of Vis light ranges from 350 to 700 nm in the spectrum (Frost and Russell, 1993). Many food components that have no or weak UV or visible absorption are analyzed with UV/Vis spectrophotometric methods after color generation through derivatization. Analyses of total phenolic, total flavonoid, total anthocyanin, and total carotenoid contents in food are good examples (Tsao and Li, 2013).

The concentration of analyte in a given sample solution can be determined by the quantitative absorption spectroscopy based on the observation that the concentration is proportional to the amount of light absorbed from a reference beam as it passes through the sample solution. The relationship between the absorbance of a solution and the concentration of the analyte is known as Beer's law (Nielsen, 2010b).

In spectroscopy or spectrophotometry, the solution of the sample must be uniform, clear, and transparent. The reference solution for food samples is normally the sample solvent, namely, water or an aqueous buffer. For good quality results, the cuvette for the measurements within the UV range should be quartz, whereas that for the Vis range can be silicate glass or inexpensive plastic cells. The best results are obtained when the wavelength is the maximum UV/Vis absorbance of the analyte and the absorbance is stable at that wavelength.

Fluorimetry

During the past 20 years, the fluorescence spectroscopy is primarily considered to be a research tool in biochemistry. The use of fluorescence now has been expanded. The fluorescence spectroscopy is similar to UV–vis, but more sensitive. The instrumentation is also similar to that of the UV–vis absorption spectroscopy, except for the optical system. In a fluorometer, there is a need for two wavelength selectors, one for the emission beam and the other for the excitation beam. Similarly, the quantitation is also based on the direct linear relationship between the fluorescence intensity and the concentration of the targeted compound in the solution. For example, the content of certain vitamins such as thiamin is determined by this method (Ball, 2005). In addition, conformation changes of a protein in a solution is studied qualitatively or quantitatively using fluorimetric methods (Lakowicz, 2009).

Infrared spectroscopy

IR spectroscopy refers to the measurement of the absorption of different frequencies of IR radiation by any food component in a solid, liquid, or gaseous state (Settle, 1997). IR spectroscopy can be categorized into near-IR of which the wavelength is 0.8–2.5 μm; mid-IR of which the wavelength is 2.5–15 μm; and far-IR of which the wavelength is 15–100 μm. The near- and mid-IR regions of the spectrum are both useful for qualitative and quantitative analysis of foods.

For food industry, the most important is attenuated total reflectance in conjunction with Fourier transform IR (FTIR) technology. It is available for the analyses of fats and oils, meats, butter, milk, even sweetened condensed milk, and juices (Downey, 1998; Van de Voort, 1992). FTIR (**Figure 7**) is convenient, rapid and automatable, and has dramatically simplified sample handling.

NIR spectroscopy is more widely used for quantitative analysis of foods than mid-IR. This technique requires much less time and is widely used throughout the production of grain and cereal products, meat and fish products, and in oilseed processing industries. NIR spectroscopy has also been used to analyze specific chemical constituents in a food, such as the total sugar content in fruit (Li-Chan *et al.*, 2011; Ozaki *et al.*, 2006), for monitoring changes that occur during processing, transportation, and storage.

Atomic absorption and emission spectroscopy

Atomic spectroscopy is widely used for accurately measuring the trace amounts of minerals in food. Although traditional

Figure 7 FTIR spectroscopy Nicolet iS10.

chemistry titration methods for mineral analysis, such as iron, chloride, calcium, and phosphorus, remain in use today, it has been largely replaced by atomic spectroscopy. In theory, virtually all of the elements in food can be measured by atomic spectroscopy.

There are two types of atomic spectroscopy, namely atomic absorption spectroscopy (AAS) and atomic emission spectroscopy (AES). AAS is based on the absorption of ultraviolet or visible radiation by free atoms in the gaseous state. Figure 8 is the photograph of AAS provided by the State Key Laboratory of Food Science and Technology of Jiangnan University. In contrast to AAS, the source of radiation in AES is the excited atoms or ions in the sample rather than an external source (Lajunen and Perämäki, 2004; Wilson and Walker, 2010).

AES has been revolutionized by adding an apparatus called ICP torch. The samples are made into an aerosol and carried into the plasma. They atomized and are excited into various higher energy levels (Clugston and Flemming, 2000; Lajunen and Perämäki, 2004). ICP–AES has a much larger analytical working range and are suitable for more elements.

Raman spectroscopy

Raman spectroscopy, a vibrational spectroscopic technique, is complementary to IR spectroscopy. It is commonly used for organic analysis. In general, the fingerprint region of organic molecules is approximately in the wavenumber range of 500–2000 cm^{-1}. Another application of this technique is in studying the changes in chemical bonding, such as when a substrate is added to an enzyme (Li-Chan *et al.*, 2011). In contrast to IR, low concentrations of organic molecules in an aqueous solution are allowed to be measured due to the weak Raman scattering of water. The instrument is shown in Figure 9.

Mass spectrometry

Mass spectrometry (MS), different from the above discussed spectroscopic techniques, is based on the detection of charged molecules or fragments of a molecule. The generated ions are separated in the electrostatic field and then finally detected according to their mass-to-charge ratio (m/z). The results from ion generation, separation, fragmentation, and detection are manifested as a mass spectrum that can be interpreted to yield molecular weight or structural information of a compound. There are different ionization methods, but electrospray ionization and atmospheric-pressure chemical ionization are two of the most frequently used methods, and both can be in either positive or negative mode (Hoffmann and Stroobant, 2013). MS is now interfaced with GC and HPLC, and the hyphenated analytical methods are powerful tools and now widely used for analyzing various food components in a mixture. Structural information for the identification of unknown compounds separated and eluted from the HPLC column can be obtained using an MS detector (McClatchey, 2002). LC–MS has played important roles in the screening and identification of bioactive compounds such as polyphenols and carotenoids in fresh foods, and in functional foods and nutraceuticals (Paré and Bélanger, 1997; Li *et al.*, 2011; Li *et al.*, 2012).

ICP-MS is a multielement analysis technology with excellent sensitivity. Atoms are first ionized and then driven into a mass spectrometer, which accelerates the ions, and separates them according to their m/z. The resolution of modern mass spectrometers is sufficient to separate ions with m/z differences (Nielsen, 2010b; Ötleş, 2011; Thomas, 2008). On the basis of the above principals, it can simultaneously measure most elements in the periodic table. In addition, even ultratrace concentrations of the samples can be detected and analyzed.

Nuclear magnetic resonance

Nuclear magnetic resonance (NMR) spectroscopy provides important structural information for a wide variety of food components. NMR instruments (Figure 10) may be configured to analyze samples in a solution or in a solid state. It may be used for the elucidation of the complete structure of complex molecules (only NMR), the 3D-imaging of fresh tissues, and the simple ingredient assays for quality assurance. The nuclei of protons (^{1}H) and the ^{13}C isotopes have a characteristic charge and spin and are most commonly used in NMR of food components. The principles and the latest applications of NMR in food analysis can be found in detail in the reference (Picó, 2012).

Figure 9 Nexion 300 ICP-MS. Photo by PerkinElmer Instruments (Shanghai) Co. Ltd. Copyright © 2013.

Figure 10 AVANCE III 400 MHz Digital NMR spectrometer.

X-ray methods

X-ray diffraction is mainly used to identify the structure of lipids, starch, as well as proteins and enzymes. The phases of lipids can also be determined by X-ray diffraction measurements. Trace amounts of metal ions in food are detected by X-ray fluorescence, whereas X-ray adsorption spectrometry is used to determine the structural environment around the metal ions in crystalline and amorphous structures (Pomeranz and Meloan, 2002).

Chromatography

Column chromatography

Chromatography has found its use in nearly all areas of food analysis. Chromatography with a very high flow rate is known as flash chromatography (FC) (Sensen, 1999). Several FC systems have been commercially available. The FC technology makes the separations easier and faster, and has been used for semipreparation of food components.

High- or ultrahigh performance liquid chromatography

Compared with conventional column chromatography, HPLC is much faster. It is a convenient and widely used technology for sugar content, pesticide residues, amino acids, toxins, organic acids, lipids, vitamins, and various phytochemicals in foods. The types of separation modes and its application in the field of carbohydrate analysis have been described in the Section Mono- and oligosaccharides. Many hydrophilic food components such as vitamin C, amino acids, phenolic compounds, and many bioactive foods are analyzed by reversed-phase HPLC, whereas both normal and reversed HPLC are used for lipophilic compounds such as vitamin E and carotenoids (Nollet, 2012; Li *et al.*, 2012). The average molecular weight of proteins and molecular weight range of polysaccharides are rapidly determined by size-exclusion chromatography. Many glycoproteins are purified using affinity chromatography (Nollet, 2012).

It is worth noting that in the past several years, two revolutionary technology advancements, the development of ultrahigh pressure pumps and sub-2-micron packing particles, have led to the state-of-the-art ultrahigh performance liquid chromatography (UPLC or UHPLC) (Waksmundzka-Hajnos and Sherma, 2011; Xu, 2013; Li *et al.*, 2012). UHPLC not only significantly reduces the sample size, analytical run time, and the solvent usage, but also produces exceptionally high sensitivity and better resolution. UHPLC is now also interfaced with MS.

Gas chromatography

GC is a separation method used to analyze thermally stable volatile substances. For example, GC has been used for the determination of fatty acids, triglycerides, flavor compounds, and many other food components, as well as pesticides, aroma compounds, polychlorinated biphenyls, and other volatile contaminants. Sample preparation is a critical step in GC analysis. It generally involves grinding, homogenization, and isolation of analytes from food samples, which may be achieved by headspace analysis, distillation, preparative chromatography, or solvent extraction. More details are mentioned in the reference (Poole, 2012).

Paper and thin-layer chromatography

Although paper chromatography is no longer widely used, TLC, because of its ease of use, relatively low cost, and greater sensitivity and reproducibility, is still used to analyze a variety of compounds in food including lipids, carbohydrates, vitamins, amino acids, and natural pigments. TLC plates with fluorescent indicators are commercially available. Compounds with UV absorption are directly detected under a UV lamp.

Other Methods

Biosensors

A biosensor is a device composed of a biological sensing element coupled to a suitable transducer. Enzyme–substrate, antibody–antigen, DNA–DNA, and aptamer–target are the most well-known interactions used in biological biosensor design. The transducers include electrochemical, optical, or a combination of the two. A wide range of biosensors has been developed for the detection of many food components such as glucose and starch, or contaminants such as carbamate, pesticides, and herbicides. The references (Joshi and Joshi, 2006; Mutlu, 2010) provide more details.

Electronic nose and tongue

Electronic nose (e-nose) and electronic tongue (e-tongue) are widely used for flavor, aroma, or odor analysis. Both techniques use different sensors for detection, and the components are grouped through pattern recognition using data analysis tools. e-Nose may use either a metal oxide semiconductor or conducting polymer as sensors that can be selective and sensitive, whereas taste sensors for e-tongue are often chemical sensors with cross-sensitivity to different components, thus lacking the sensitivity and selectivity. It should be pointed out that none of these techniques provide compositional information of a food sample, but rather profiles of different types of compounds. Using a solid-phase microextraction probe, the headspace gas can be absorbed onto the fiber and injected to a GC or GC–MS for compositional analysis. Some applications

of e-nose and e-tongue in food analysis are discussed in the references (Berger, 2007; Deisingh *et al.*, 2004).

Ultrasound

Ultrasound is a nondestructive testing method for characterizing food composition, monitoring some unit operations during production, and elucidating molecular processes in foods. Ultrasound is highly flexible and can be applied in an online environment allowing real-time observation of the changes in the product structure under processing conditions. More examples are described in the reference (Irudayaraj and Reh, 2008).

Electrophoresis

Electrophoresis is a technology that separates proteins according to the migration of charged molecules in a solution through an electric field. Each protein separated in a nondenaturing system has a characteristic mobility determined by a combination of the intrinsic charges located on the protein surface combined with physical characteristics such as shape and molecular weight (Walker and Rapley, 2008). Unlike nondenaturing electrophoresis, sodium dodecyl sulfate-PAGE is used to separate protein subunits only by size.

Modern instrument such as capillary electrophoresis has been developed and used for protein separation and analysis, as well as for some artificial sweeteners and preservatives in soft drinks. Niacin in food is determined by capillary zone electrophoresis (Perrett, 2002). More examples of instrumental analysis are described in the reference (Pomeranz and Meloan, 2002).

Conclusion

Advances in food science and technology have brought innovations and improvements in the analytical methods or techniques used to ensure food safety, quality, and nutrition-related research and actual applications along the food production chain. Fundamental discussions such as those on the comprehensive reviews on well-established conventional chemical, physical, and microbiological methods were included in this article; furthermore, recent advances in sensorial, bioanalytical, and instrumental analysis techniques and their applications have also been addressed. Applications and their pros and cons of these novel technologies in the analysis of the food components and additives including carbohydrates, proteins, lipids, trace elements, vitamins, toxins, contaminants, and residues have been discussed. Technologies related to the physical and chemical properties of food such as texture, rheology, and color are also important aspects for food-related research and development. Introduction to novel technologies and approaches, such as the noninvasive and nondestructive methods such as NMR, ultrasound, biosensor and e-nose and e-tongue, is believed to provide insights into future trends in food analysis.

Glossary

Electroporation Pore formation in the membrane of biological cells caused by the application of an external electric field.

Hurdle concept The principle of applying combined methods in order to have a series of preservation methods resulting in multitarget effects for microbial inactivation.

Plasma Quasi-neutral gas generated by coupling energy to a gaseous medium in order to dissociate the gaseous component molecules into a collection of ions, electrons, charge-neutral gas molecules, and other species.

Protective culture Target microorganisms inoculated to food matrix with consequent *in situ* production of inhibitory molecules or competitive effect against pathogen and spoilage bacteria.

Volumetric heating Heat generation inside a product rather than conduction from the outside due to dissipation of electrical energy (Ohmic heating) or electromagnetic energy (Microwave heating).

Needs and Principles for Food Safety and Food Preservation

The production of safe food with improved sensorial and nutritional quality at low cost remains the key challenge within food processing. Shelf life extension technologies play a major role in order to achieve this task. The avoidance of unnecessary overprocessing requires the design of improved processes and process conditions need to be controlled with much greater precision.

In general, pasteurization is used to inactivate vegetative germs. Therefore, usually continuous heat treatment between 65 and 90 °C for 0.5 s and 30 min, respectively, is needed (Wilbey, 1996, 2003). To inactivate heat-resistant forms of microorganisms, like bacterial endospores, thermal sterilization is used. Sterilization in food preservation describes a technique to provide commercial sterility meaning that the product has to be free from microorganisms that are either capable of producing food poisoning toxins or cause food spoilage during the product's shelf life (Ababouch, 1999). To realize these conditions, it is understood that a treatment is needed, which insures atleast an inactivation effect similar to 3 min holding time at 121 °C. Therefore, packaged products are treated discontinuously at temperatures ranging from 120 to 125 °C for 5–20 min (Berry and Pflug, 2003; Ramesh, 1999), whereas modern out-of-pack ultrahigh temperature (UHT) treatments usually combine rapid continuous flow steam heating (130–150 °C), short holding periods (2–15 s), and subsequent aseptic packaging (Kumar *et al.*, 2012; Swartzel, 2003).

However, excessive thermal treatments indeed cause remarkable losses in sensory and nutritional quality and affect noticeably structural and rheological product properties (James and James, 2003; Nicoli *et al.*, 1997). For these reasons it is aimed to apply as less heat as possible in a preservation treatment, by insuring the necessary level of food safety at the same time.

To find appropriate heat treatments, liquid and high-moisture foods are divided by definition into low-acid foods (pH > 4.6) and acid foods (pH < 4.6). The basis for this classification is the inability of *Clostridium botulinum* to germinate, grow, or produce toxin below pH 4.6. Yet, in products of pH between 4.6 and 4.0 the survival and growth of some spore-forming Bacillaceae (*Bacillus coagulans*, *Bacillus macerans*) and butyric anaerobes like *Clostridium butyricum* have to be controlled. Therefore, products with pH of 4.0 or higher, such as dairy products or vegetable juices, are usually sterilized. Microorganisms, which are able to germinate in acidic environments of pH lower than 3.7, are commonly inactivated by pasteurization (Berry and Pflug, 2003). Examples are lactic acid bacteria, yeasts, or molds (Rajashekhara *et al.*, 2000). Owing to these facts, acidic products with pH of 4.0 or below are usually pasteurized, which preserves valuable product compounds in comparison with sterilization (Ababouch, 1999). Nevertheless, some heat-resistant molds produce ascospores, which can outlive standard pasteurization processes and additionally are able to grow out at pH levels lower than 4.0 (Taniwaki, 1995). These abilities make them a high risk, especially in production of fruit-based products (Beuchat and Rice, 1979; Houbraken *et al.*, 2006; Nguyen, 2012), and therefore are the reason for further extension of the applied thermal load.

Many different preservation techniques are applied. Each of the used technologies is based on certain preservation factors or inactivation mechanisms. These preservation factors can be biological, chemical, or physical. The most important preservation factors for foods to extend the shelf life during storage are high or low temperatures, acidity, water activity, chemical agents, or redox potential. Traditional preservation techniques, such as dehydration or salting of food, as well as the common practice of refrigerated storage target at one of those preservation factors in order to avoid the growth of microbial population in food as well as to minimize chemical reactions. Traditional preservation techniques are mainly based on a single preservative effect, are used in high intensity, and are especially an issue for thermal sterilization treatments, which are excessively used for preservation of ambient liquid foods. Owing to these facts, the

idea of the so-called hurdle concept is a promising concept in order to lower losses in sensory and nutritional quality by raising safety of processed foods at the same time.

To lower the mentioned high treatment intensities, the so-called hurdle effect can be used. In detail the hurdle effect describes the synergetic effect of combined preservation technologies using different mechanisms for inactivation or inhibition of undesirable microorganisms (Leistner, 1978). Based on this effect, the hurdle technology was developed. The hurdle technology describes a concept for planned microbial spoilage control, shelf life extension, and quality improvement of preserved food. The main assumption is that the treatment intensity of each applied preservation technique can be lowered by use of the right combination of hurdles. For these reasons the application of the hurdle concept can help to apply gentler preservation treatments, especially by use of nonthermal preservation techniques (Ross *et al.*, 2003), possibly in combination with mild thermal energy inputs. Hereby applicability, effectiveness, and combination of hurdles are dependent on target organisms, product, process, and raw materials (Leistner, 1992, 1994, 2000; Leistner and Gorris, 1995).

Hence, the below sections aim to give an overview on existing technologies with a focus on inactivation and decontamination processing technologies as indicated in **Table 1**. Intrinsic hurdles, such as modification of pH or water activity, in order to avoid the growth of microorganisms are also potential concepts to extend the shelf life of foods but are not discussed in this article.

Microbial Inactivation Indices and Inactivation Kinetics

Inactivation indices as well as inactivation kinetics can be used to describe a given process. As an example, thermal pasteurization is defined as a food that is free of vegetative microorganisms, excluding thermoresistant. This condition or requirement can be achieved by a reference heat treatment of, i.e., 62.8 °C for 30 min for milk and up to 68.3 °C for 30 min for eggnog and frozen dessert mixes. In case of pasteurization of juice, for example, apple juice from concentrate, a treatment of 71 °C for 6 s should be applied (FDA, 2013). Depending on the target pathogenic microorganism to be eliminated and on the food matrix, alternative process conditions may be applied. Alternative thermal treatments can then be estimated on the basis of the following two thermal indices, *D*- and *z*-values. *D*-value is defined as the time required to reduce 90% of a given microorganism at a given temperature; *z*-value is the temperature variation giving a 10 times variation of *D*-value. Both parameters, *D*- and *z*-values, allow estimating alternative process conditions as defined by a linearity between temperature and time. Because the elimination of pathogenic microorganisms depends not only on temperature and time but also on food matrix, the microbial characteristics and process design and the use of inactivation kinetics have facilitated the estimation of adequate processes conditions. In addition, the nonlinearity inactivation phenomena (mainly due to hurdles combination, nonthermal inactivation effects, and food in-homogeneities), and several chemical reactions affecting quality attributes of the food have made from kinetics a valuable tool to design tailored food processes.

Numerous experimental results have been fitted to proposed kinetic models, mainly to describe the evolution of the microbial inactivation as a function of process parameters, i.e., temperature, pressure, electric field strength, etc. The main mechanism of microbial inactivation is related to several chemical or physical mechanisms depending on the inactivation technology applied. Mechanistic models for the microbial inactivation have rarely been combined with kinetic models to give one single predictive model that is capable of describing the expected microbial inactivation based on the mechanism of inactivation. In contrast to this, several empirical models have been developed, which can be widely found in the literature. A detailed description of the main inactivation kinetics can be found in the following sections. Empirical models based on Huelsheger *et al.* (1981) and Peleg (1995) and those that follow a Weibull distribution (Van Loey *et al.*, 2002; Weibull, 1951) have preferably been used to model the microbial inactivation by the various emerging technologies. An example of different models is given next:

First-order exponential decay:

$$S(t) = e^{-kt} \quad [1]$$

Table 1 Examples of preservation technologies depending on the state of food

Product type	*Liquid*	*Semisolid*	*Solid*
Pasteurization	Conventional thermal	Conventional thermal	Conventional thermal (e.g., baking and frying)
	Pulsed electric field	Microwave	Microwave
	High pressure (HP)	Ohmic heating	
	Filtration	HP	
Sterilization	Ultrahigh temperature (direct/indirect)	Retort	Retort
	Filtration	Pressure-assisted thermal sterilization (PATS)	PATS
		Ohmic heating	Cold plasma (surface)
		Microwave	Irradiation
Product examples	Dairy/Juices	Paste and puree with/without pieces	Meat/seafood Fruit and vegetables Cereals/herbs

Huelsheger model (Huelsheger *et al.*, 1981):

$$S(t) = \left(\frac{t}{t_c}\right)^{\frac{-(\phi-\phi_c)}{k}} \quad [2]$$

where S is the survival rate (survival microbial concentration/initial microbial concentration), t is the treatment time, t_c the critical treatment time, ϕ is a process parameter (i.e., temperature or pressure), ϕ_c is the value of the previous selected process parameter at the extrapolated survival fraction of 100%, and k is a constant characteristic of each microorganism.

Peleg model (Peleg, 1995):

$$S(t) = \frac{1}{1 + \exp\left[\frac{\left(\phi-\phi_{c(n)}\right)}{k_{(n)}}\right]} \quad [3]$$

$\phi_{c(n)}$ is a process parameter (i.e., temperature or pressure) at which the survival level is 50% and $k_{(n)}$ is a kinetic constant describing the steepness of the sigmoid curve.

Weibull distribution (Weibull, 1951):

$$S(t) = \left(-\frac{t}{\delta}\right)^{\alpha} \quad [4]$$

where δ is the time needed for the first decimal reduction, α is a shape parameter, and t is the processing time. Additionally, δ and α depend on process parameters and an additional equation may be needed to describe the behavior of both as a function of the most influent process parameter.

The existence of two populations of microorganisms (sensitive and resistant subpopulations) or the existence of inhomogeneities of process parameters within a given treatment chamber has made it difficult to describe the inactivation rate with a single equation. Instead, several equations have been modified in order to fit the obtained experimental results. Special attention should be paid when considering single models as it is not possible to easily distinguish between the inactivation mechanisms and the inhomogeneities of the process parameters. Weibull, *n*th-order, exponential and Churchill models, and modifications of them have been adapted in order to account both populations, the resistants and the weak ones. An example of a modified model is an extension of the exponential equation (Amiali *et al.*, 2004; Pruitt and Kamau, 1993):

$$S(t) = \beta_1 + (1-\beta_1)e^{-\beta_2 t} \quad [5]$$

$$S(t) = \beta_1 e^{-\beta_1 t} + (1-\beta_1)e^{-\beta_2 t} \quad [6]$$

where $S(t)$ is the fraction of total survivors; t, the treatment time; β_1, the fraction of survivors in population 1 (generally related to the sensitive population); β_1, the specific death rate of subpopulation 1; and β_2, the specific death rate of subpopulation 2.

Another widely used model is the modified Weibull equation:

$$\log_{10}(S) = \beta_1\left(\frac{t}{\delta_1}\right)^{\alpha_1} - (1-\beta_1)\left(\frac{t}{\delta_2}\right)^{\alpha_2} \quad [7]$$

To validate the accuracy of a given kinetic model, the degree of fit for the obtained equations can be analyzed according to the coefficient of determination (R^2), root mean square error (RMSE), bias factor (B_f), and accuracy factor (A_f).

The RMSE is defined as an error between predicted and experimental microbial survival values. The RMSE is a statistical measure of the differences between values predicted by a model and the values actually observed from experiments and can be expressed by an absolute value. The B_f is a measure of overprediction ($B_f > 1$) or underprediction ($B_f < 1$) of the predicted values by the empirical model in comparison with the experimental values. The accuracy factor (A_f) indicates how the predictions differ from the observed data. An A_f of 1 indicates perfect agreement between all predicted and observed values. An A_f value higher than 1 (e.g., 1.13) shows that the prediction is on an average either 13% smaller (if $B_f < 1$) or 13% larger (if $B_f > 1$) than the observed values (Ongeng *et al.*, 2010). The A_f should thus be analyzed always in combination with the B_f.

According to the best fitting parameters, the best kinetic models should be chosen. However, differences in the experimental setup and enzymes or microorganisms from varying sources make it difficult to validate existing kinetic models. Thus, it is worth mentioning that a kinetic model should be elaborated and used for a specific case and not for similar applications.

Food Quality Aspects during Preservation and Shelf Life Considerations

The shelf life of a food product can be defined as the period during which the product is still acceptable for human consumption. The shelf life is determined by microbial, chemical, and physical aspects. As a result of these aspects, consumers may reject the product based on its sensory characteristics. The shelf life is in most cases determined by a combination of raw material quality, product formulation, processing, packaging, and storage conditions. Special attention should be paid to storage conditions, as temperature and oxygen content may faster or delay chemical reactions as well as microbial growth. The storage temperature directly affects enzymes. Enzyme activity in food may result in a change of the chemical composition of the product, resulting in changes in flavor, odor, color, and texture. The amount of oxygen may gather chemical reactions and thus cause oxidation.

Thermal treatments are the most used methods to extend the shelf life of liquid foods by inactivation of microorganisms and enzymes; however, heat causes irreversible losses of nutritional compounds, undesirable changes in physicochemical properties, and alteration of their antioxidant properties (Plaza *et al.*, 2006; Wang and Xu, 2007). Thus, the application of nonthermal technologies or the combination of modified atmospheres and active packaging has been widely used. The application of any thermal or nonthermal pasteurization technology requires accurately defined treatment intensity, followed by a predictable microbial inactivation as well as a minimal impact on heat-sensitive compounds. The development of each single chemical, physical, or microbiological change can additionally be described by mathematical models,

i.e., growing of microorganisms and vitamin degradation during the whole storage period. A mathematical model can thus be used to predict the shelf life or for determination of the conservation conditions that result in the desired shelf life.

The microbial growing of microorganisms, yeast, and molds during the shelf life can be fitted to the Gompertz's equation. Zwietering *et al.* (1990) reported that the Gompertz's model was statistically sufficient to describe microbial growth data:

$$\log_{10}\left(\frac{N}{N_0}\right) = A\exp\left(-\exp\left(\frac{\mu_m e}{A}(\lambda - t) + 1\right)\right) \quad [8]$$

where μm [Δlog10(CFU ml^{-1})/day] represents the maximum specific growth rate, λ(day) represents the stage adaptation of the microorganism to the environment in which it is, A is the maximum diameter reached by the colony (mm), and e is a constant (2.7182). The longer the adaptation phase and the lower the maximum specific growth rate, the better for the industry (Zimmermann *et al.*, 2011).

The above-described equation is a potential tool in order to determine the shelf life of a certain product as a function of spoilage microorganisms, but it does not give any indication about how to control or design the process variables of the killing step. A good approach for determining best process conditions followed by the best storage conditions is the combination of microbial inactivation kinetics models with the Gompertz's model, as described by Boon *et al.* (2010), in which a predictive shelf life model for orange juice treated by high pressure (HP) and pulsed electric field (PEF) processing was described by combining inactivation and shelf life kinetics. The model can be applied to predict the shelf life based on microbial and enzymatic spoilage and to determine the processing conditions to obtain the desired shelf life. The model combines microbial inactivation and growth with enzyme inactivation, enzyme rest activity, and quality.

Food Preservation Technologies

Thermal Food Preservation

One of the oldest industrial sterilization of food is canning (Prescott and Underwood, 1897; Prescott and Underwood, 1898). Canning involves heating hermetically sealed containers to at least 121 °C for low-acid foods, which requires a pressure vessel or retort (Larousse and Brown, 1997). High-acid foods are sterilized at lower temperatures after filling or may be hot filled. Packaging formats for retorting are metal cans, glass jars, and plastic or paperboard composite containers. Compared with other preservation techniques, canning is relatively inexpensive and the quality of meats, fruits, and vegetables is adequate for most consumers (Lopez, 1987). Products are shelf stable and ready to eat. Process improvements have been achieved by hydrostatic retorts, rotary or shaking retorts, or packaging innovations, such as two-piece cans or the use of pouches.

Pouches for retort were developed by Natick Labs of the US Department of Defense as an improved military ration, replacing small, single-serve metal cans. The retort pouch is a flexible container made of laminated polymer films with an aluminum foil barrier layer to protect against light and oxygen. The critical development was a sealant layer of polypropylene that could withstand the elevated temperatures of pressure cooking. The narrow profile of the package was also presumed to provide improved flavor and texture quality compared with a cylindrical can of the same volume due to reduced overcooking.

The limited strength of these flexible packages represents an engineering challenge because internal pressure develops inside the packages during thermal processing as a result of internal water vapor pressure and the expansion of entrapped gases with increasing temperature. This internal pressure will become greater than the saturation pressure of the steam in the retort and can cause packages to burst unless an overriding air pressure is applied in the retort. Profiles of overriding air pressure required during the retorting of foods in flexible packages are largely determined by trial and error. Recently, online detecting devices are in use in order to allow an accurate control of air pressure. Recent developments in retorting mainly concern improved methods for calculating optimum retort process conditions of time and temperature as well as the introduction of automation and robotics in materials handling operations on the cook room floor in major food plants.

As an in-pack sterilization process, canning has some limitations with regard to the heat transfer, especially for larger cans that lead to some overprocessing until the cold spot has reached the targeted sterilization conditions. Out-of-pack sterilization represents a more gentle option in order to better maintain the product quality when assuring food safety. Aseptic processing and packaging involves sterilizing foods and containers separately before filling the sterile containers in a sterile environment. Because foods are cooled before filling, containers do not need the strength to resist high temperatures and pressures, as do containers used in canning. This makes packaging less expensive and a larger diversity of packaging materials exist – lightweight plastics, paperboard laminates, and large polymer bags, for instance. Containers are sterilized in a variety of ways: by chemicals (hydrogen peroxide) for paperboard, by irradiation for bags, and by the heat of thermoforming for plastic tubs. The sterile environment is created by steam or chemical sterilization and maintained by sterile air filtration.

Depending on the type of food, the concentration and size of particles, and the viscosity, foods are sterilized by heat in scraped surface heat exchangers, tubular heat exchangers, or plate heat exchangers and cooled with similar equipment. Low-viscous products are suitable for direct UHT heating methods, such as steam injection and steam infusion. Foods with particulates require special care in sterilization to ensure that the center temperatures reach the minimum required for the type of food (Ramaswamy *et al.*, 1997). The flavor and texture of aseptically processed foods may be superior to that of postpackage-processed foods, due to a less severe heat treatment, but the big advantage of in-pack processing is low-cost packaging. Capital cost is higher than that for equivalent canning capacity because filling rates are generally slower for aseptics and the equipment controls are more complex.

Both of the above-discussed technologies, canning as well as conventional aseptic UHT processing, have some limitations with regard to the speed of heating as well as with regard to the processing of high viscous food containing large

particles. To overcome these constraints, volumetric heating methods are gaining interest for pasteurization and sterilization. Ohmic heating and microwave heating represent promising solutions.

Ohmic heating involves the conversion of electrical energy into thermal energy. The food is exposed to the electric field in direct contact with electrodes. Depending on the electric field strength, electrical conductivity of the product, and electrode configuration, an electrical current flows that causes volumetric heating based on the Joule effect. Ohmic heating is commonly applied in a continuous system where the product is pumped through a set of electrodes. The fast heating can be used for pasteurization as well as for sterilization of products depending on the energy input. In-pack application of Ohmic heating is also under development and involves the use of packaging materials with electrically conductive parts in order to transfer the electrical current into the product. To avoid electrochemical reactions, an alternating current with a frequency >20 kHz is favorable and currently used in the available industrial equipment. With regard to product composition, the distribution of the electrical conductivity is the key property in order to allow a homogeneous heating. Product fractions with a higher electrical conductivity due to higher salt content heat faster. Therefore, adaptation of the electrical conductivity of the solid and liquid phase and between different particle fractions is required. Otherwise, hot spots and cold spots will occur at locations of high and low electrical conductivity, respectively (Larkin and Spinak, 1996; Parrott, 1992).

Microwave heating is a common method for heating food in the kitchen, although industrial applications for food pasteurization and sterilization are also emerging. Recently, microwave heating has been investigated as a fast heating method for pumpable foods in a continuous system. In addition, in-pack sterilization concepts using microwave heating are developed. Microwaves and radio frequencies are forms of electromagnetic energy that interact with water molecules and ions in the food and heat material from the inside as compared with other forms of heat transfer in which energy is supplied from the surface. The result can be very fast and selective heating. However, some desirable reactions in cooking, such as browning, may not occur.

Nondirect Thermal Preservation

To lower the thermal load of preserved food products, several approaches for nonthermal inactivation of microorganisms have been introduced over the past 20 years. In general nonthermal technologies are able to inactivate microorganisms at sublethal temperatures by use of alternative inactivation methods. Among proposed techniques, pulsed electric fields, high hydrostatic pressure, ionizing irradiation, pulsed light, or cold plasma have to be mentioned (Butz and Tauscher, 2002; Knorr *et al.*, 2011a). However, most of these techniques still require very high treatment intensities, depending on the treated product and the expected target organisms (Ross *et al.*, 2003). The effectiveness concerning spore inactivation in particular has to be considered very carefully for each of the mentioned technologies and methods, as possible inactivation mechanisms are not yet totally understood in most cases.

High pressure processing

High pressure processing (HPP) is often regarded as the leading nonthermal preservation technology. During the past decade, HPP has emerged as a viable commercial alternative for pasteurization of value-added fruits, vegetables, meat, ready-to-eat food, and seafood products. This cold pasteurization process is used in more than 190 industrial-scale installations worldwide, which produce more than 300 000 tons of product per year (Tonello Samson, C. 2012, NC Hiperbaric, Spain, personal communication). In most cases HPP is used for food safety reasons or to extend the shelf life (Knorr *et al.*, 2011b), but there are numerous other interesting applications of HP, such as food structure engineering and the reduction of the allergenic potential of, for example, rice (Knorr *et al.*, 2006; Sharma and Yadav, 2008).

However, the primary aim of treating foods with HPP is to reduce or eliminate relevant foodborne microorganism and pathogens (Patterson *et al.*, 2007). Typically, ambient temperatures, pressures up to 600 MPa, and treatment times from a few seconds to several minutes are used to kill bacteria while preserving quality related factors like vitamins, pigments, and flavor components (Oey *et al.*, 2008). During the inactivation of microorganisms and quality-related enzymes, changes in the functionality of food proteins as well as in the structure of food system or texture can occur (Knorr, 2002).

The reasons for these phenomena are diverse; in general the primary structure of low molecular weight molecules, like peptides, lipids, vitamins, and saccharides, is rarely affected by isostatic HP because of the very low compressibility of covalent bonds at pressures below 2 GPa (Cheftel and Culioli, 1997; Gross and Jaenicke, 1994; Oey *et al.*, 2008). Conversely, the native structure of macromolecules, such as starch, can be changed by HP, and thermally induced structural changes can also occur. Pressure, as a basic thermodynamic parameter, affects these biomolecules and can change the state of molecular organization (e.g., crystallization of fats or phase changes of phospholipids) (Macdonald, 1992). In food systems such changes can be either positive (e.g., inactivation of microorganisms or gel formation) or negative (e.g., texture defects). These HP effects are governed by three general principles, which are outlined below:

1. The principle of Le Chatelier and Braun states that if a chemical system at equilibrium experiences a change, the equilibrium will shift in order to minimize that change. If this change is an increase of pressure, any phenomenon that is accompanied by a decrease in reaction volume (e.g., chemical reactions, phase transitions, or changes in the molecular configuration) is enhanced and vice versa (Cheftel, 1995). Hence, HP will shift the equilibrium toward the system with the lowest volume. Moreover, when the activation volume (ΔV^*) of an activated complex is smaller than that of the initial reactants, a pressure increase and a temperature decrease will increase the reaction rate constant k_{kinetic} and therefore also the reaction rate, according to Equation 9

$$\ln k_{\text{kinetic}} = \ln k_0 - \Delta V^* \frac{p}{RT} \qquad [9]$$

where p is pressure, T is temperature, and R is the molar gas constant. However, an increase in temperature also

increases the rate of reaction according to the Arrhenius law (Cheftel, 1995).
2. The isostatic principle implies that pressure is instantaneous and uniform and is transmitted independently of the geometry and size throughout the whole biological sample (Balny, 2004).
3. The microscopic ordering principle means that at a constant temperature an increase of pressure increases the degree of the molecular ordering of a substance (Urrutia Benet, 2005).

The main reason for the dynamic behavior of biomolecules under pressure is the free volume of the system, which is expected to decrease with increasing pressure (Heremans, 2002).

HP can, therefore, induce reversible or irreversible changes in the native structure of proteins, starches, and other macromolecules, which are similar to changes occurring at heat and in the presence of chemicals, but the residual molecular structure after a pressure treatment can vary significantly. In this regard, Knorr *et al.* (2006) published a detailed review of pressure-induced changes in the structure of proteins, and Jaeger *et al.* (2012) reviewed the impact of these on food structure.

The specific pressure effects on microorganism are more complex and several different mechanisms leading to cell death interact if HPs at ambient temperatures are applied. Primarily, HP at a sufficient high level can induce enzyme inactivation and cell membrane rupture caused by a phase transition of the membrane (Abe, 2013; Ananta *et al.*, 2005; Winter and Jeworrek, 2009). The pressure level needed to achieve a 5 $\log_{10}$ reduction of pathogenic microorganism in different food products range from 300 to 800 MPa (Hendrickx and Knorr, 2002) and often a synergism between pressure and temperature is reported (Buckow and Heinz, 2008). By increasing the process pressure, it is possible to decrease the needed temperature level to achieve the same inactivation. According to Smelt *et al.* (2001) the pressure-induced effects leading to cell death of vegetative microorganisms can be attributed to four factors:

1. Protein and enzyme unfolding, including partial or complete denaturation
2. Cell membranes undergo a phase transition and solidify under pressure
3. Disintegration of ribosomes in their subunits and
4. Intracellular pH changes, which are related to the inactivation of enzymes and membrane damage (Knorr *et al.*, 2011b).

Bacterial endospores show in this regard a much higher pressure and temperature resistance. The process conditions used for the cold pasteurization of solid, semisolid, and liquid foods are insufficient to achieve a sterilization and hence an extended shelf life at ambient temperatures. A combination of HP (>500 MPa) and elevated initial product temperatures ($>80\ ^{\circ}C$) can be a promising approach to produce high-quality low-acid foods (Reineke *et al.*, 2013).

Pulsed electric field

PEF treatment is a nonthermal alternative to conventional thermal pasteurization for liquid products. Other applications of PEF are the disintegration of plant or animal raw materials or the induction of stress responses in biological cells. According to several studies, the quality of a PEF-pasteurized food product is closer to that of the fresh product than to that of the heat-pasteurized product, and the safety of the fresh product is enhanced by the inactivation of vegetative pathogenic microorganisms. The first commercial PEF application was installed in 2005 in the United States for fruit juice preservation. Clearance of the FDA was already available since 1996, indicating the techniques potential for safe and gentle preservation (Barbosa-Cánovas *et al.*, 1999).

PEF technology can be used to induce nonthermal permeabilization of cell membranes. Depending on the treatment intensity (external electric field strength, number, and duration of the electric pulses) and cell properties (size, shape, orientation, and conductivity), the pore formation may be permanent or temporary (**Figure 1**).

The treatment consists of the application of very short electric pulses (1–100 μs) at electric field intensities in the range of 0.1–1 kV cm^{-1} (reversible permeabilization for stress induction in plant cells), 0.5–3 kV cm^{-1} (irreversible permeabilization of plant and animal tissue), and 15–40 kV cm^{-1} for the irreversible permeabilization of microbial cells. The aforementioned field intensities lead to the formation of a critical transmembrane potential, which is regarded to be the precondition for cell membrane breakdown and electroporation (Rubinsky, 2010).

The temperature at which the cells are exposed to the electric field has a significant influence on membrane fluidity properties and therefore on physical stability of the cell membrane. The liquid crystalline structure of the phospholipid bilayer at elevated temperature facilitates pore formation and increases PEF treatment effectiveness, leading to a synergetic effect of PEF and elevated temperature (Lelieveld *et al.*, 2007; Raso and Heinz, 2007).

High-intensity electric pulses can be generated by the switched discharge of a suitable capacitor bank. A schematic drawing of an electrical circuit for the generation of high-intensity electric field pulses is given in **Figure 2**. The characteristics of the discharge circuit determine the shape of the time-dependent potential in the treatment chamber. Exponential decay pulses represent a complete discharge of the capacity. A rectangular shape of the pulse can be produced by using special switches, capable of interrupting the current at high potentials, or by the implementation of a pulse forming network. If an additional capacitor is used together with a parallel switch, bipolar pulses can be obtained (Loeffler, 2006).

The geometry of the treatment chamber has a considerable effect on the electric field distribution and on the total resistance and therewith on the discharge circuit. The treatment chamber design needs to be optimized, taking also into account a homogenous distribution of the electric field strength as well as the characteristics of the fluid flow, the viscosity, and the particle sizes.

Various treatment chamber designs, such as parallel plates, coaxial cylinders, or colinear configurations, have been used for PEF processing and some modifications of these basic designs have been proposed. A comprehensive overview of different treatment chamber configurations can be found in Huang and Wang (2009).

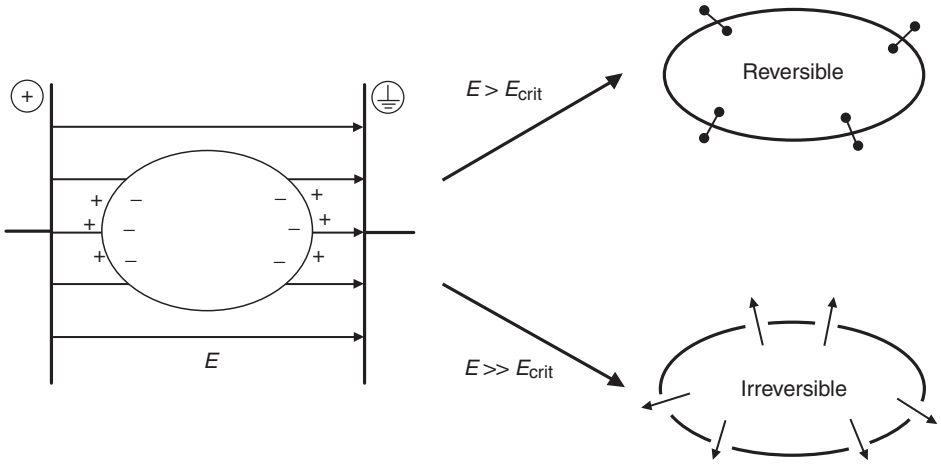

Figure 1 Exposure of biological cells to an external electrical field that results in reversible or irreversible pore formation.

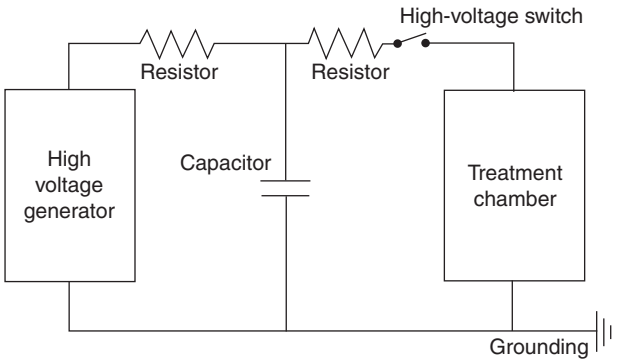

Figure 2 Schematic drawing of an electrical circuit for the generation of high-intensity electric field pulses.

Although the PEF treatment is considered as a nonthermal food processing technology with the electroporation being the main inactivation mechanism, there is a significant temperature increase during high-intensity PEF treatment, as applied for pasteurization purposes due to Ohmic heating effects. Many authors have described the temperature distribution in a PEF treatment chamber and reported the occurrence of high local temperatures due to inhomogeneous field distribution of the electrical field, limited flow velocity, and recirculation of the liquid (Gerlach *et al.*, 2008; Jaeger *et al.*, 2009a; Lindgren, 2001; Lindgren *et al.*, 2002). This is of particular importance when discussing PEF effects on functionality of heat-sensitive compounds, such as proteins, or when conducting inactivation kinetic studies. Additional thermal effects may occur in case of application of high total energy inputs, insufficient temperature control, or unfavorable treatment chamber design. Treatment homogeneity and the avoidance of overprocessing of the product, including the occurrence of local high temperatures due to Ohmic heating effects, are the key aspects to guarantee predictable microbial inactivation while maintaining heat-sensitive food constituents.

Effective inactivation for most of the spoilage and pathogenic microorganisms has been shown and colony count reductions depending on treatment intensity, product properties, and type of microorganism in the range of 4–6 log-cycles are comparable to traditional thermal pasteurization. Most of the studies conducted in the past showed that PEF is effective only against vegetative microorganisms, yeasts, and molds as well as mold ascospores but ineffective against bacterial endospores and viruses (Lelieveld *et al.*, 2007).

The factors that affect microbial inactivation during PEF treatment are process factors, such as electric field intensity, pulse width and shape, treatment time, and temperature; microbial factors, such as type, shape, size, concentration, and growth stage of microorganism; and media factors, such as pH, antimicrobials and ionic compounds, electrical conductivity, and medium ionic strength.

Membrane damage and inactivation of microorganisms due to PEF was at first considered as an all-or-nothing event, but a differentiated approach is required even if the critical parameters for the electrical breakdown of cell membranes are exceeded. Membrane damage and sublethal injury was found to be repairable under certain conditions and the extent to which cells repair their injuries was reported to depend on the treatment intensity, the microorganism, and the treatment medium pH. On the one hand, sublethally injured cell fractions are a risk from a food quality and safety point of view, because these cells may recover and regain their initial vitality. On the other hand,

sublethally injured fractions have a potential for subsequent complete inactivation by the application of additional hurdles, such as suboptimal storage conditions or the application of other inactivation methods, such as the application of antimicrobials or other food preservation technologies (Garcia *et al.*, 2005; Jaeger *et al.*, 2009b; Somolinos *et al.*, 2008).

The microbial inactivation rates differ considerably between inactivation in simple media and inactivation in a complex matrix. This was partly attributed to the protective effect of some food compounds, such as xanthan (Ho *et al.*, 1995), proteins (Jaeger *et al.*, 2009b; Sampedro *et al.*, 2006), or fat (Grahl and Märkl, 1996). In addition, model microorganisms used in most of the studies and the way of sample preparation differ significantly from the native state of the microbial population present in the real food system. The diverse and heterogeneous microbial flora present in real foods is not comparable to inoculated microorganisms in most cases due to strong variability of microbial species and physiological state of microorganisms. The consideration of microbial growth state, adaptation to the treatment media, and the existence of inhomogeneous microbial populations with less sensitive subpopulations seem to be the most challenging aspects when transferring inactivation results to real products and industrial implementation.

The evaluation of the effect of PEF on food compounds is complex. Available reports are limited and different experimental setups and processing parameters make them difficult to compare. The consideration of electric field side effects, such as temperature increase and temperature hot spots due to Joule heating effects within a nonuniform electric field and the occurrence of electrochemical reactions and pH shifts, is the most challenging aspect within this context. The nonthermal inactivation of microorganisms by PEF is based on the electroporation of membrane structures. High-intensity electric fields are unlikely to affect covalent chemical bonds, but the electric field application and related side effects may show an impact on food compounds; moreover, process modifications toward the inactivation of microorganisms and enzyme structures are also possible. Owing to the application of PEF, changes in the conformational state of proteins might cause changes in protein structure and enzyme activity. A comprehensive overview of PEF effect on food material properties can be found in Van Loey *et al.* (2002) and Jaeger *et al.* (2012).

Irradiation

Electromagnetic waves of high frequency and corpuscular rays have bactericidal effects. In the past century extensive research has been carried out to evaluate the use of irradiation for sterilizing food. Possible process applications range from influencing the ripening process of fruit and vegetables to a nonthermal sterilization of food. Hence, the irradiation of food is gaining more and more attention in the past few years. Today, health and safety authorities in more than 45 countries have approved irradiation of more than 70 different foods, ranging from spices to grains, from deboned poultry meat to ground beef, over to fruits, nuts, and vegetables (Sommers and Fan, 2006). The irradiation process involves exposing the food matrix, either packaged or in bulk, to controlled amounts of ionizing radiation for a predetermined time. During the process and in dependence on the irradiation dose, microorganisms, vegetative bacteria, bacterial spores, viruses, and insects that might be present in the food are inactivated. The irradiation process does not increase the normal radioactivity level of the treated food (Kessler, 2002).

The main lethal effect of irradiation is the induction of structural changes in the DNA. Irradiated microorganisms can no longer proliferate and cause food spoilage. Insects do not survive or become incapable of proliferation (CAST, 1989). Plants are unable to continue the natural ripening or aging process. The specialty of processing food by ionizing radiation is that the energy density per atomic transition is very high; it can cleave covalent bonds in molecules and induce ionization, which is not achieved by mere heating. This is the reason for both new effects and new concerns. The treatment of solid food by ionizing radiation can provide an effect similar to heat pasteurization of liquids, such as milk or fruit juice (Kessler, 2002; Lakritz *et al.*, 1989).

For food irradiation electron beams and gamma rays are used. Gamma radiation is radiation of photons in the gamma part of the electromagnetic spectrum. The radiation is obtained through the use of radioisotopes, generally cobalt-60 or, in theory, cesium-137. The advantage of gamma rays with regard to food irradiation is the deeper penetration depth compared with electron irradiation. For electron irradiation, electrons are accelerated in an electric field to a velocity close to the speed of light. Electrons are particulate radiation and hence have cross-section many times larger than photons, so that they do not penetrate the product beyond a few inches, depending on product density. Electron beams are, therefore, more suitable for flat thin products (up to 5 cm) and gamma rays for larger size bodies up to 30 cm thickness (Kessler, 2002).

The dose of radiation is measured in the SI unit known as Gray (Gy). One Gy dose of radiation is equal to 1 J of energy absorbed per kilogram of food material. In radiation processing of foods, the doses are generally measured in kGy (1000 Gy). 'Dose' is the physical quantity governing the radiation processing of food.

The application is generally divided into three main categories based on the dose (Kessler, 2002):

Up to 1 kGy: Low-Dose Applications

- Sprout inhibition in bulbs and tubers 0.03–0.15 kGy,
- Delay in fruit ripening 0.25–0.75 kGy,
- Insect disinfestation, including quarantine treatment and elimination of foodborne parasites 0.07–1.00 kGy.

1–10 kGy: Medium-Dose Applications

- Reduction of spoilage microbes to prolong shelf life of meat, poultry, and seafood under refrigeration 1.50–3.00 kGy.
- Reduction of pathogenic microbes in fresh and frozen meat, poultry, and seafood 3.00–7.00 kGy.
- Reducing the number of microorganisms in spices to improve hygienic quality 10.00 kGy.

Above 10 kGy: High-Dose Applications

- Sterilization of packaged meat, poultry, and their products that are shelf stable without refrigeration. 25.00–70.00 kGy.
- Sterilization of Hospital diets 25.00–70.00 kGy.

Table 2 Membrane filtration technologies and its possible applications

Filtration technology	*Application for separation*	*Pore size (nm)*
Microfiltration I	Microorganisms fat globules	10^3–10^4
Microfiltration II	Casein micelles	25–130
Ultrafiltration	Proteins	3–5
Nanofiltration	Sugars (mono- and disaccharides)	~0.8
Reverse osmosis	Mineral salts, cations, and anions	~0.4
	Water	~0.3

Source: Compiled from Kessler, H.G., 2002. Food and Bio Process Engineering – Dairy Technology. Munich: Verlag A Kessler.

Pathogenic microorganisms, such as *Escherichia coli* O157: H7, *Salmonella*, *Campylobacter jejuni*, *Listeria monocytogenes*, and *Vibrio*, are sensitive to low levels of ionizing radiation. With increasing irradiation dose the lethal effect on microorganisms is more intense, but a higher dose, although not creating any harmful products, may simultaneously introduce changes in sensory qualities. Therefore, a balance must be attained between the optimum dose required to achieve the desired objective with a minimum impact on the sensory quality of the processed food (Sommers and Fan, 2006).

With the combination of low-dose irradiation and refrigeration, the shelf life of several fruits and vegetables, meat, poultry, and fish can be prolonged considerably without altering the flavor or texture of the food. Spoilage microorganisms, such as *Pseudomonas* spp. and *Salmonella*, are relatively sensitive to irradiation at a dose of 2.5 kGy applied to fresh poultry carcasses processed according to good manufacturing practices (FDA, 1997). When properly refrigerated, the meat shelf life can double (provided it is kept below 5 °C). Further the short shelf life of some fruit can be increased by slowing down the ripening. For example, ripening in bananas, mangoes, and papayas can be delayed by irradiation at 0.25–1 kGy. However, the extension achieved depends on the initial quality of the fresh food. The time of harvest and the physiological state also affects the response of fruits and vegetables to irradiation. Indeed, not all fruits and vegetables are suitable for irradiation because they undergo undesirable changes, like off-flavors or changes in texture and color (Kessler, 2002; Sommers and Fan, 2006).

Filtration

The filtration process is a mechanical or physical operation, that is used for the separation of solids from fluids or fluids from a gas phase by interposing a medium through which only the fluid/gas can pass. Oversize solids in the fluid are retained in the so-called retentate and the filtrated fluid that passes through the filter membrane is called permeate. Based on the particle size, which is retained in the retentate, one could distinguish between microfiltration, ultrafiltration, nanofiltration, reverse osmosis/hyperfiltration, electrolysis, and ion exchange. With regard to shelf life extension of liquid food, microfiltration is the common filtration process to remove most of the microorganisms, whereas the other membrane filtration technologies can be used to remove food constitutes (Table 2).

In the case of microfiltration, the main purpose is the removal of microbial cells from solutions and is hence operated with pore diameters larger than those required by ultrafiltration. This ensures higher permeation rates, without compromising the retention of microorganisms. The membranes employed have mean pore diameters of 0.05–5 μm and are made of zirconium and aluminum oxides, which makes them mechanically and thermally more stable (Kessler, 2002). Hence, they can be heat sterilized and can handle the whole pH range of liquid foods and cleaning agents.

For the separation of microorganisms from beverages, like wine, cider, mineral water or soft drinks, and milk, pore sizes in the range of 0.8–1.4 μm are commonly used. For the processing of milk in particular, a strong interest for minimally processed products with extended shelf life is present. Whereas high-temperature short-time pasteurized milk has a storage quality of approximately a week at cold storage, ultra-high temperature (UHT) milk can be held at room temperatures for several months. However, the UHT processing of milk is accompanied with undesired thermally derived product alterations, like cook flavor, off-flavor, and caramel flavor (Mehta, 1980). Therefore, the extended shelf life (ESL) milk with taste like fresh milk, but a prolonged shelf life of up to 4 weeks in the cold chain distribution, was introduced into the market by a combination of microfiltration and heat pasteurization. By applying this method, raw milk is separated into skimmed milk and milk fat. The skimmed milk is microfiltrated through ceramic membranes and subsequently pasteurized. The milk fat, together with the germ-enriched skim milk retentate, is processed by ultrahigh heat treatment and then reverted into the skimmed milk (Schmidt *et al.*, 2012). By microfiltration, bacterial counts can be reduced by 4–6 $\log_{10}$ (Elwell and Barbano, 2006; Schmidt *et al.*, 2012). Interestingly, microfiltration can lead to a shift of the microbial population of the ESL milk compared with heat pasteurized milk, because of a disproportionately high retention of Gram-negative bacteria, which may be due to generally larger cell size of Gram-negative compared with that of Gram-positive or lactic acid bacteria (Schmidt *et al.*, 2012).

Consequently, the combination of microfiltration and heat pasteurization has a remarkable potential for the production of high-quality ESL milk. With regard to other beverages, like beer or fruit juice, a microfiltration alone could be sufficient to achieve a 'cold' pasteurization (Kessler, 2002).

Antimicrobials in Food Preservation

In the past years, an increased consumer's demand for sophisticated foods, with an additional health-promoting benefit

above basic nutrition, has been seen. To fulfill this goal and to ensure the consumers safety and provide food with an acceptable shelf life, the addition of antimicrobials could be a part of a hurdle concept. This includes not only traditional methods for food preservation, such as salting and smoking, but also the bioconversion of raw products during the fermentation or the addition of natural or artificial antimicrobials.

Natural antimicrobials

Most perishable food are stored at low temperature and are often packaged under modified atmosphere in order to extend their shelf life. However, these hurdles for microbial growth do not eliminate undesirable microorganisms from the product. Besides the technologies introduced above to control and inactivate pathogens, a wide range of food grade chemicals could be added during the food manufacturing process to extend the shelf life by stabilizing chemical changes in the food or by preventing or inhibiting microbial growth. These secondary preservatives include traditional and natural antimicrobials with potential or current value for its use in foods (Holley and Patel, 2005; Naidu, 2000). Because of the consumer awareness regarding synthetic chemical additives, foods preserved with natural additives have become popular and led researches to look for natural food additives with a broad antimicrobial spectrum.

Natural antimicrobials are derived from animal, plant, or microbial sources and until now more than 1340 plants with defined antimicrobial compounds have been identified. The antimicrobial compounds present in these plants were identified as phenols, alcohols, aldehydes, ketones, ethers, and hydrocarbons (Tajkarimi *et al.*, 2010). Antimicrobials from plant origin are obtained by various methods, which include steam distillation and hydro distillation as well as supercritical fluid extraction. Hence, the extracted essential oil fraction is often a mixture of several compounds. However, traditional food ingredients, like some spices and herbs, also have antimicrobial effects on human pathogens (Brandi *et al.*, 2006). The antimicrobial effects of clove, mint, ginger, garlic, cinnamon, and mustard have been known for centuries and are still in use as an antimicrobial hurdle. Further, bay leaf, coriander, cumin, oregano, rosemary, sage, and thyme have been reported to have significant bacteriostatic properties (Tajkarimi *et al.*, 2010). Despite its contribution to taste and flavor, plant extracts and spices can act against Gram-positive pathogens, such as *L. monocytogenes*. Essential oils derived from plants and spices showed antimicrobial activity against *L. monocytogenes*, *Salmonella typhimurium*, *E. coli* O157:H7, *Shigella dysenteriae*, *Bacillus cereus*, and *Staphylococcus aureus* at levels between 0.2 and 10 $\mu l\ ml^{-1}$ (Burt, 2004). For example, a combination of mild heat treatment and the addition of cinnamon and clove essential oils to apple cider significantly reduced the time to achieve a 5 $\log_{10}$ inactivation of *E. coli* O157:H7 (Knight and Mckellar, 2007). Further, Mosqueda-Melgar *et al.* (2008) achieved a pasteurization (>5 $\log_{10}$ reduction of *Salmonella enterica*) of tomato juice by a combination of 2.0% of citric acid or up to 0.1% of cinnamon bark oil and a PEF treatment.

A promising recent development for the use of natural antimicrobials is its incorporation into packing materials, rather than in the food itself, to protect the food surface. The advantage of this approach is, among others, that the sensory and chemical compatibility of the antimicrobial with the target food plays a secondary role.

Fermentation and protective cultures

A special case of an antimicrobial hurdle is the fermentation of food, where microorganisms produce lactic or acetic acid, which lowers the pH value of the product and hence extends its shelf life. The mankind uses fermentation to increase the hygiene and storability of food for more than 10 000 years. Hence, the food fermentation process underwent continuous improvements and microbial cultures became an essential component in food production.

In modern food production, fermentation is defined as a process of biotransformation carried out by microorganisms or their enzymes, irrespective of whether it is based on fermentation in the classical sense (with an anaerobic catabolism of organic substrates without the involvement of exogenous electron acceptors) or oxidative metabolism (respiration) (Vogel *et al.*, 2011). For fermentation, thermally treated or untreated food raw materials from plant or animal origin are used. By addition of certain microorganisms or mixtures of microorganisms to the food, its appearance odor and color are significantly changed and the shelf life is extended (Kessler, 2002). Fermented foods cover a broad range of products, including fermented dairy products, like yoghurt and cheese, vinegar, alcoholic beverages, sourdough, pickles and sauerkraut, fermented olives, or soy sauce. In total, approximately one-third of all food currently being consumed is fermented.

Fermented products have some unique features and a number of advantages, compared with the untreated raw product or the product treated with other preservation technologies. This includes a high degree of hygienic safety, because of, for example, the production of alcohol or a decrease of the pH value, which significantly increases the shelf life. Raw materials are refined by improving quality-determining properties. Further, harmful or toxic substances derived from raw materials, such as cyanides, goitrogens, proteinase inhibitors, phytic acid, oxalic acid, glucosinolates, and indigestible carbohydrates, are partly degraded (Vogel *et al.*, 2011). Moreover, fermented products meet the demand for natural and organic foods and they have low energy consumption during production, whereby it could be regarded as an ecologically friendly preservation technology.

The development of fermented foods was determined by the fact that originally a special microbial community developed under the ecological conditions present in the respective substrate. Such spontaneous fermentations are still in use for the production of olives, pickles, sauerkraut, or kimchee. For the industrial-scale formation of, for example, beverages and dairy products, defined cultures/starter cultures are used, which allow a greater control of the fermentation process. In this regard, starter cultures are defined as preparations of live microorganisms or their resting forms, whose metabolic activity has desired effects in the fermentation substrate/food

(Vogel *et al.*, 2011). Mäyrä-Mäkinen and Bigret (1998) further specified starter cultures into:

- Single strain cultures: contain one strain of a species.
- Multistrain cultures: contain more than one strain of a single species (e.g., a mixture of different *Lactobacillus* strains).
- Multistrain mixed cultures: contain different strains from different species.

The use of starter culture has some benefits, compared with spontaneous fermentation or an 'old-new inoculation' with in-house strains, which, for example, entails the risk of selecting *Listeria* in red smear cheeses (Bockelmann *et al.*, 2005). Starter cultures allow a uniform and high-quality food production in large scale, with controlled fermentation times and a reduced hygienic risk (Vogel *et al.*, 2011).

A special case of food fermentation is the use of protective cultures, for example, for fermented sausages like salami. The discovery that certain strains are competitive, and in particular that they can also inhibit pathogenic and toxigenic microorganisms, opens up the possibility that these strains can be used for food production. Hence, protective cultures are added to food with the aim of reducing risks by pathogenic microorganisms. Its effectiveness follows two principles. The first is the competitive exclusion, for example, through a competition for nutrients and binding sides/space for growth on the substrate or through a better adaption to the oxygen content. The second is the formation of antagonistically active substances, for example, the formation of organic acids (e.g., lactic, acetic, propionic, and formic acids) by lactobacilli or the production of ethanol, CO_2, and bacteriocins (compounds like Nisin) as well as antibiotics or other antimicrobial substances (Kessler, 2002; Vogel *et al.*, 2011).

Modified atmosphere packaging

Food packaging serves to protect a product against deteriorative effects, protects it against mechanical stress, communicates to the consumer as a marketing tool, and provides the consumer with ease of use and convenience (McMillen, 2008). To increase the shelf life of packaged food, different techniques can be applied. However, one of the most interesting application is the modified atmosphere packaging (MAP), because of the high demand of additive-free products.

MAP packaging is the removal or replacement of the atmosphere surrounding the product before sealing in vapor barrier materials (McMillin *et al.*, 1999). The proportion of gas inside the package can be changed passively, by properly using semipermeable materials, or actively, by using specific gas mixtures, together with semipermeable or impermeable packaging materials (Amanatidou, 2001). MAP can as well be a vacuum packing, which removes most of the air before the product is enclosed in barrier materials.

During active modification of the packaging atmosphere, first the air is removed by vacuum or flushing and later replaced with another gas mixture before sealing the package. The main gases used in mixture are CO_2, N_2, and O_2, but the potential of other gases (i.e., CO, Ar, or O_3) has been investigated as well (Zagory and Kadar, 1988). The optimal gas composition and storage conditions depend on the type of product and desired effect, which is often a slowing down of the respiration rate to reduce produce metabolism and maturation. For example, in fresh-cut vegetables the respiration rate is reduced by employing a gaseous atmosphere with an O_2 level low enough to maintain basic produce metabolism and using refrigeration temperatures as low as possible (often between 2 and 8 °C). The final shelf life of these MAP-packed products could be extended by 5–7 days (Amanatidou, 2001). High concentrations of O_2 (60–85%) are recommended for the MAP storage of poultry and fresh meet. The positive effects of high O_2 concentrations in muscle products is related to color retention of red meat, minimized drip losses, and inhibition of anaerobic microorganisms (McMillen, 2008). However, the shelf life of meat products further depends on the presence of CO_2. To minimize the risk of growth of anaerobic pathogens (i.e., *C. botulinum*) in fish products, lower O_2 concentrations ($\sim$30%) are recommended often in combination with higher CO_2 concentrations. On the contrary, it has been suggested to exclude O_2 for fatty fish products to minimize rancidity caused by lipid peroxidation.

Hence, the MAP packaging has to be adapted to the product, but if done correctly it could be a significant part of a hurdle concept to extend the shelf life of minimally processed products.

Surface Decontamination

Cold atmospheric plasma

Plasma is an ionized gas and also called the fourth state of matter. For the formation a plasma, a gas can be heated or an excess of free electrons is needed to displace electrons in the atoms and molecules of the bulk gas. The plasma can be described as a quasineutral particle system in the form of gaseous or fluid-like mixtures of free electrons and ion, frequently containing neutral particles (atoms and molecules), activated and metastable species (NO_x*), and free radicals like reactive oxygen species and reactive nitrogen species (Knorr *et al.*, 2011a; Rutscher, 2008). In the field of plasma research one can find a complex nomenclature considering the temperature of the electrons and the bulk gas and the surrounding pressure (Roth, 1995). In nonthermal plasmas, the electron temperature is much higher than the bulk gas temperature. Although the electron can reach several ten thousands K, the gas temperature remains at temperature levels below 40 °C (Knorr *et al.*, 2011a; Mastwijk and Nierop Groot, 2010). Most plasma source are operated in a vacuum; however, the most suitable system for food processing is an atmospheric pressure plasma device where no extreme conditions are required, low process temperatures are possible, and no evaporation of water from high-moisture food products occurs.

The industrial use of applied plasma technology in the nonfood sector is diverse (e.g., cost-effective light sources, high-definition large flat panel displays, and plasma-improved printability of foils). Much work has already been done in the field of plasma medicine and related topics, like tissue sterilization or blood coagulation (Fridman *et al.*, 2006). However, the first approaches in the field of food surface decontamination are published in the past years. These studies primarily focus on the inactivation of unwanted microorganisms on

heat-sensitive foods, such as fresh fruit and vegetables, meat, and eggs, where conventional thermal decontamination methods are more or less unsuitable. Plasma treatment is also regarded as a potential alternative to other chemical (e.g., chlorine treatment) or physical methods (e.g., HP, PEF, and ionizing irradiation). Advantages of plasma processes are high efficiency at low temperatures (generally $<70\ ^{\circ}C$); precise generation of plasmas suitable for the intended use; just in time production of the acting agent; low impact on the internal product matrix; application free of water or solvents; absence of residues; and their being resource efficient (Schluter *et al.*, 2013).

The presence of UV-emitting species, charged particles, and free radicals is associated with the antimicrobial effect of the plasma (Laroussi, 2005). The capability of nonthermal atmospheric plasmas to inactivate vegetative cells, including Gram-negative and Gram-positive bacteria, yeast, fungi, biofilm formers, and endospores, was shown in various studies (Moreau *et al.*, 2008). Recent interest is focused mainly on the inactivation efficiency of cold plasma with respect to contaminated pericarps of mangoes, melons, bell pepper, freshcut fruit surfaces, almonds, and eggs (Ragni *et al.*, 2010). However, the inactivation mechanisms of different plasmas are not yet fully understood. Depending on the plasma source, process parameters, and process gases the reactive species vary within the plasma, which makes inactivation mechanisms difficult to compare.

Recent research activities focus mainly on inactivation of microorganisms, but little is known about the effect of plasma on food matrices. Emitted reactive species not only react with bacteria but also affect food components, such as water, lipids, proteins, and carbohydrates (Keener, 2008), and have an effect on phenolic compounds, at least in lamp lettuces (Grzegorzewski *et al.*, 2010).

In the past decade, concerted research efforts were expended to understand and to apply atmospheric pressure plasmas as surface decontamination and sterilization method. Modular and selective plasma sources were developed. These combine the technological advantages of atmospheric pressure plasmas (avoidance of vacuum devices and batch processing) with the flexibility and handling properties of modular devices (Ehlbeck *et al.*, 2008). This technological progress may enable plasma applications in food processing in the near future. However, further investigations are required to characterize the plasma applied and to better understand the interactions of reactive species with organic surfaces as well as vital biosystems (Mastwijk and Nierop Groot, 2010). This will allow us to control the effects of plasma and to design highly specified and efficient plasma processes.

Steam

Natural microbial contamination in dried food, such as almonds, nuts, spices, seeds, cocoa beans, and cereal products, is found mainly at the surface of those foods. Microorganisms are not able to grow in low water activity environments; however, cells may survive. In addition, significant food safety risk may occur when contamination takes place after a lethal processing step, cross-contamination being one of the main causes of *Salmonella* contamination (Podolak *et al.*, 2010). Application of inactivation technologies is a powerful tool to eliminate or reduce the level of natural microbial contamination. However, without the implementation of good manufacturing practices, well hygienic designed equipment, and postcontrol lethality areas, the use of inactivation technologies could not guarantee a safe food production.

Commonly used processes for the decontamination of dried products are hot air, microwaves, radiofrequencies, or Joule-heating treatments. The application of heat on dried food often induces organoleptic degradation or achieves only a low destruction rate. It has also been well documented that heat resistance of microorganisms significantly increase with a decrease in water activity (McCann *et al.*, 2009; Staack *et al.*, 2010). The heat resistance at low water activity contents may correlate with the presence of a specific microflora adapted to harsh environment conditions. In addition, proteins become more stable when in a dry state during heat treatment (Hansen and Riemann, 1963). Moreover, water availability has also a great impact on the transfer of heat to microorganisms (Laroche *et al.*, 2005). The increase in resistance of vegetative cells to heat as a function of water activity has been studied by several authors (Bera *et al.*, 1998; Brown and Melling, 1971; Corry, 1973; Daemen, 1981; Laroche *et al.*, 2005).

In the case of pasteurization of almonds, all pasteurization technologies are evaluated by the ABC's technical expert review panel for their ability to provide a minimum 4-log reduction in *Salmonella* contamination and to demonstrate no significant degradation to the sensory, quality, and nutritional characteristics of almonds. Based on a risk assessment conducted for the ABC and reviewed by the FDA, it has been determined and implemented in 1 September 2007 that a 4-log reduction is an appropriate level of control (Almond Board of California, 2012).

The use of steam may help increasing the microbial inactivation of dried food products. The underlying mechanism of steam inactivation is based on increasing the water activity where bacteria are located: at the surface of the food. However, in order to avoid excess of steam condensation and an increase of final food moisture, the application of steam should be carefully done and thus the design of processes should allow a controlled steam condensation only at the surface of dried foods.

The processing of particulate food crops consists of several process steps. As an example, the following steps describe the adequate application of steam and its controlled condensation at the surface of dried foods (Perren and Fischer, 2009):

1. First, the product surface temperature is increased to a level right below the equilibrium temperature of the subsequent process step. To preheat, it is appropriate to use dry heat. This step allows conditioning the food and avoiding an excessive water condensation. If no preheating is applied, risks of increasing the food moisture and a larger heat impact on food quality properties might occur.
2. Second, the product is transferred into a preheated pressure vessel. In this vessel, a default pressure below atmospheric pressure is established and steam is induced into the product, whereas the pressure is maintained constant. To equilibrate the surface temperature of the product to the evaporation temperature of the system, a minor quantity of water condenses on the surface forming a surface water film. This water film allows increasing the water activity and

thus creating an environment adequate to transfer heat and faster bacterial inactivation.

3. Third, after equilibrium is achieved, the process continues for a given duration, until the desired inactivation of the microorganisms is accomplished.
4. Finally, the steam injection is stopped and the system pressure is further reduced in order to evaporate excessive surface moisture. Thus, the food is restored to its initial condition as it was before the controlled condensation process.

Minimized treatment times are possible only on the basis of the unique combination of HP, high temperature, and high humidity. An optimized combination of the above parameters may allow the inactivation of pathogenic and even thermophilic vegetative microorganisms and their spores within a very short time to below detection limits.

Conclusion

The tailored preservation of food involves the selection of a suitable processing technology according to the characteristics of the food as well as according to processing targets, such as relevant spoilage microorganisms and desired shelf life conditions. It was shown that available technologies differ widely in their ability to inactivate vegetative cells and spores inside or on the surface of a food product. Traditional thermal processing was often found to negatively affect food quality of sensitive products, which led to the development of more gentle processing technologies applying advanced heating principles or using nonthermal inactivation mechanisms. Process validation remains the key challenge in order to assure the suitable selection of processing conditions and the consideration of food characteristics covering aspects such as the presence of particles as well as the distribution of salt affecting the heating properties during Ohmic or microwave sterilization. The profound knowledge of the relevant process–product interactions will allow the successful application of existing processing concepts and will lead to further innovations toward a targeted food preservation.

Rice and Food Security in Asia

Rice, a staple for nearly half of the world's seven billion population, is grown in more than 100 countries. However, more than 90% of rice is produced and consumed in Asia, where it constitutes the basic staple for majority of the population, including the region's 560 million hungry people. As a poor man's food, rice is a sensitive topic in many countries; governments can 'make or break' with the fall and rise of rice prices. In many of these countries, rice is deeply engraved into their rich culture and tradition. Asian countries also take immense pride in having a vibrant rice farming system, and the reaffirmation of many countries after the 2008 rice crisis to revamp domestic rice sector and achieve food security through rice self-sufficiency is a good example of what rice means to many countries in the region.

The introduction of high-yielding varieties in the late 1960s, which marked the beginning of the Green Revolution, has more than tripled Asian rice production in the past four decades, from 200 million tons (paddy equivalent) in early 1960s to above 600 million tons in 2010. This has been possible with the introduction of modern varieties in tandem with assured irrigation, subsidized inputs (such as fertilizer, fuel, and pesticide), and guaranteed prices. During this period, more than 1000 modern varieties have been released to farmers in Asian countries with the adoption from 30% in 1970 to approximately 70% in 1990 (IFPRI, 2002).

The success of the Green Revolution in the early 1960s witnessed steady rise in Asia's per capita rice consumption from 85 kg in the early 1960s to approximately 100 kg by 2010; however, global per capita consumption rose from 50 to 65 kg during the same period (Figure 1). The rising per capita consumption in combination with growing population resulted in tripling of total Asian rice consumption during this period from 150 to 450 million tons (milled equivalent).

In line with rising rice consumption, per capita calorie intake also increased by more than 40% from 1891 in 1960 to 2706 in 2009. Similarly, life expectancy and infant mortality also witnessed significant improvements during the post-Green Revolution era. Although the contribution of rice to total calorie intake has dropped in Asia during this period (from 38% in 1970 to 29% in 2009), it still accounts for 45–70% of total calorie intake in many rice-consuming countries in the region including Bangladesh, Cambodia, Vietnam, Indonesia, and many other Asian countries (Figure 2).

Changing Consumption Patterns

Since the early 1990s, strong economic growth in many Asian countries, particularly in China and India, snapped the upward trend in Asian per capita rice consumption as consumers diversified their diet from rice to high-value products, such as meat, dairy products, fruits, and vegetables. Between 1992 and 2005 per capita rice consumption in Asia declined from 103 to 96 kg. Similarly, per capita rice consumption in India also declined after economic liberalization in the early 1990s. In both these countries, per capita consumption declined by 10 and 8 kg, respectively, during this period. Despite such decline in per capita consumption in heavyweights like China and India, the total consumption in Asia has continued to rise on the basis of population growth and rising per capita consumption in other Asian countries.

However, the declining trend in per capita rice consumption in heavyweights like China, India, and Indonesia has been snapped in recent years and per capita consumption has started rising again (Figure 3). This reversal in trend has contributed to the recent surge in total Asian global consumption: 40 million tons in 7 years. Household consumer expenditure data collected by India's National Sample Survey Organization also confirm the flattening in per capita consumption in recent years from the declining trend in the 1990s in all four regions in India.

In other Asian countries, such as Bangladesh and the Philippines, per capita consumption remains strong across income groups both in urban and rural areas. National representative household consumption survey data collected between 2000 and 2010 both from the Philippines (Family Income and Expenditure Survey) and Bangladesh (Household Income and Expenditure Survey) confirm the trend. Even high-income group population both in rural and urban areas is found to consume more rice with rise in income. Unlike the Philippines and Bangladesh, per capita rice consumption is on a downward trend in few other Asian countries including Thailand, Vietnam, and Malaysia.

Future Consumption Trends

As one looks ahead, income growth, urbanization, and other long-term social and economic transformations are likely to influence the composition of food basket in the future. Normally, one would expect diversification away from rice to more high-value products, such as meat, dairy products, fruits, and vegetables in the diet as the income rises. But the diversification rate in many Asian countries will also be influenced by the extent of government interventions in price control and subsidized food grain distribution.

India is a good example, where the government has rolled out an elaborate food subsidy program to provide highly subsidized food grains (rice and wheat) for 65 million below-poverty-line households, including nearly free food grains to 20 million Antyodaya Anna Yojna (AAY) households, the poorest of the poor households. Each of the 65 million households is provided 35 kg of grains every month at 74–86% below the procurement cost (Sharma, 2012). The above poverty line (APL) families are also given 15–35 kg of grain every month depending on the availability at less subsidized

prices. In 2011/12, the food subsidy bill amounted to approximately Rs 72 823 crores (US$14 billion) (Sharma, 2012).

Thus it would be a mistake to bundle all Asian countries together and project them to behave like Japan and South Korea as they get wealthier. Each Asian country will be unique in the way it diversifies its consumption pattern as incomes rise. For a country such as India with a large number of vegetarians, it is unrealistic to assume that their rice consumption will follow the patterns of the Korean, Japanese, and Taiwanese populations with rising standards of living. Even other developing Asian countries, such as Bangladesh, the Philippines, and Vietnam are likely to adopt consumption patterns different from what has been witnessed in the past. Overall, it may be reasonable to assume that the diversification away from rice will be slow in many Asian countries and the minimum threshold level of rice consumption for each country will be different.

Additionally, 700 billion mouths will have to be fed in the next 30 years, based on United Nation's 2010 population projections, when the Asian population reaches close to the 5 billion mark in 2035 and 5.15 billion by the mid-century. If Asian per capita rice consumption follows the trend it has seen in the past two decades, then total consumption will grow at the rate of population growth. The total consumption growth may even exceed population growth if the recent uptrend in per capita consumption in 'big three' countries (China, India, and Indonesia) continue in the future.

The bottom line message is that if diversification in Asia is slow and not widespread then it is almost certain that the total demand for rice in Asia will continue to rise in the future. However, the opposite will be true and total Asian consumption may start declining if Asian countries follow rapid diversification path. A recent study by Seck *et al.* (2012) projected global rice consumption to rise from 439 million tons (milled rice) in 2010 to 496 million tons in 2020, and it will further increase to 555 million tons in 2035. Among the various rice-consuming regions, Asian rice consumption is projected to account for 67% of the total increase, rising from 388 million tons in 2010 to 465 million tons in 2035.

Future Supply Prospects

In the first three decades of the Green Revolution, the higher productivity growth of more than 2% annually provided incentives for farmers to bring in additional areas into rice production. Part of the area expansion has been possible due to greater cropping intensity through the adoption of short-duration varieties. A combination of productivity growth and area expansion provided the needed production growth to keep rice prices affordable and meet the global needs. However, in the past decade, yield growth has significantly slowed down: less than 1% in recent years. The effect is already evident with two food price spikes in the past 5 years and steady rise in rice prices in the past decade. From 2001 to 2007, rice prices nearly doubled, primarily because of the supply–demand imbalance. Between November 2007 and May 2008, the rice market witnessed the tripling of international rice prices. Although prices went down quickly after May 2008, they have settled at a much higher level of US$500–600 per ton as compared with US$300–400 per ton before the crisis.

The current rice area is at an all time high at approximately 160 million hectares as compared to 120 million hectares in the early 1960s. Further expansion of rice area in the future is not a viable option for most Asian rice-growing countries, where additional land is no longer available and pressure on the existing rice land from urbanization and other non-agricultural uses is growing rapidly. This is particularly true for China, India, Indonesia, Thailand, the Philippines, and Bangladesh, which account for approximately 70% of global rice

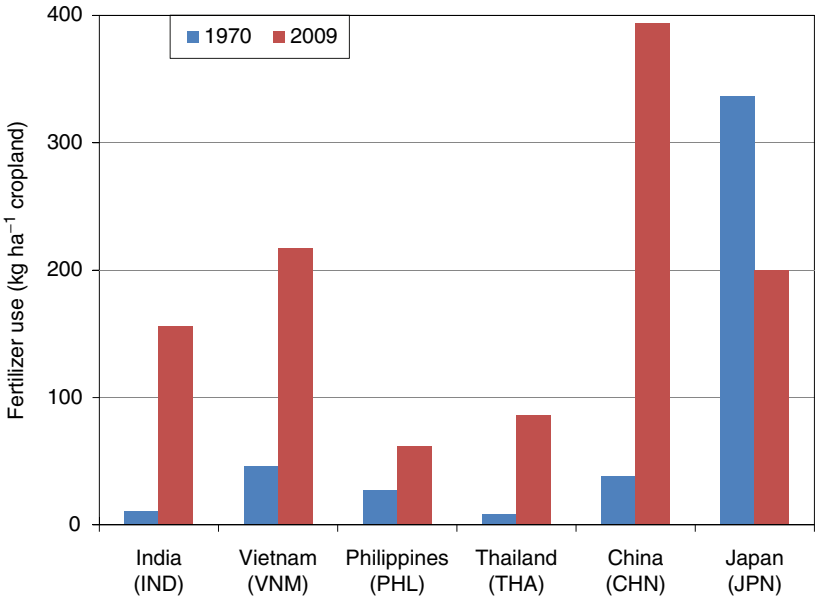

Figure 4 Fertilizer (NPK) use in agriculture, 1970–2009. Reproduced from International Fertilizer Industry Association (IFA) and FAO.

production and consumption. For example, China's rice area has declined by more than 5 million hectares (15%) in the past 3 decades and the downtrend may continue in the future. Although a similar downtrend has not been evident in other rice-growing countries in the region because of government interventions, it is hard to foresee how governments can continue with such interventions in the face of rising costs, water shortages, and growing pressure from competing sectors.

The few exceptions could be countries such as Cambodia and Myanmar, which were left out of the Green Revolution for varying reasons but they could be stimulated to expand rice production by developing infrastructure and providing better market linkages.

Without the possibility of further area expansion in the future, yield growth will have to be revamped to approximately 1.5% annually to be able to meet growing global needs and keep prices affordable. But unfortunately, the approaches adopted that led to the success of the first Green Revolution may not be applicable now. During the first Green Revolution, many Asian countries provided incentives to the farmers through subsidized inputs and assured markets for their products to expand rice production. Farmers responded by adopting input–responsive high-yielding modern varieties and bringing additional land into crop production.

Fertilizer use in Asian countries has increased markedly in the past four decades (Figure 4). In China, fertilizer application per hectare in NPK equivalent has increased from 38 kg in 1970 to approximately 400 kg in 2009. Similarly, Vietnam has witnessed a five-fold increase in fertilizer use during this period from 46 kg in 1970 to 217 kg in 2009. Fertilizer use in India has gone up significantly during this period but still remains low as compared to China and Vietnam at 156 kg ha^{-1}. However, the variations among Indian states are still very large. The problem is much more severe in frontline Green Revolution states of Punjab and Haryana where NPK use per hectare is 200 kg ha^{-1} as compared to 50 kg for Orissa and 10 kg for Arunachal Pradesh, the states mostly left behind by the Green Revolution.

Similarly, use of ground water for irrigation purpose has also increased in many Asian countries, more notably in India, Indonesia, and Bangladesh. In case of India, water withdrawal for agriculture increased by more than 70% in the past three decades (Figure 5). Similarly, agricultural water withdrawal has gone up by approximately 25% in Indonesia between 1990 and 2000. In a recent study published in *Nature*, Rodell *et al.* (2009) concluded that groundwater use for irrigation in northwestern India is not sustainable. According to this study, the water table in this part of India is declining by 4 cm $year^{-1}$. Thus, yields improvements in the future needs to be achieved in the face of these emerging constraints including land and water scarcity, environmental degradation, and rising input prices.

Climate Change

Apart from various constraints described above, the anticipated change in global climate in the form of rising temperature, increasing amount of carbon dioxide in the atmosphere, greater frequency of extreme weather events (e.g., floods and droughts), and greater incidence of pest and diseases are likely to make things more complicated for rice production in the future. A large share of rice production is already lost to various abiotic (flood, drought, and salinity) and biotic stresses (pests and diseases). Among abiotic stresses, drought is the largest constraint, affecting nearly a third of the total rice area in Asia (Venuprasad *et al.*, 2008) and causing significant economic losses to poor rice producers in the region. According to Pandey and Bhandari (2007), average production loss due to drought in three regions: eastern India, northeast Thailand, and southern China adds up to US$200 million annually. Similarly, flood is another abiotic stress that

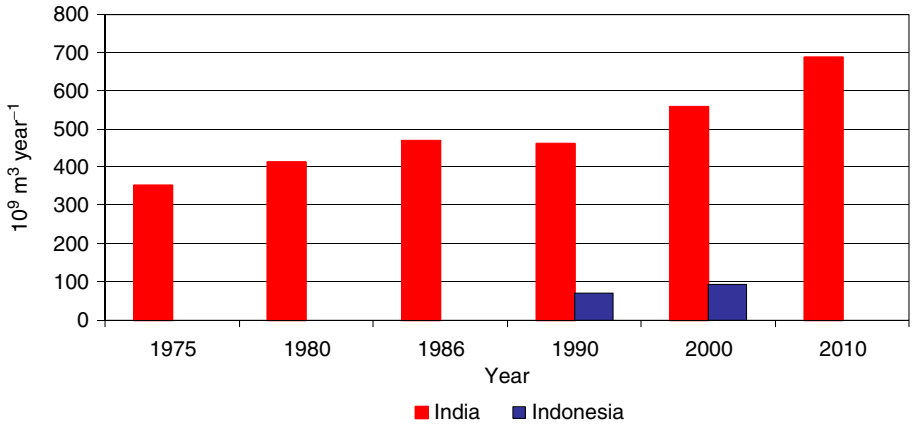

Figure 5 Agricultural water withdrawal. Reproduced from FAO AQUASTAT database.

regularly causes severe rice yield damage on 16 million hectares of flood-prone rice area in Asia (Johnson *et al.*, 2012). The annual loss in rice production in South Asia alone is estimated to be 4 million tons (IRRI, 2010). Salinity, though not as big a stress as drought and flood, still affects 10 million hectares of coastal and inland areas (Johnson *et al.*, 2012). But growing rice is the only option available to farmers in the saline-prone coastal regions where nothing else can be grown; this crop is critical to the food security of these resource-poor farmers.

Crop losses are likely to be lot greater in the future with changing climate that will make flood, drought, and salinity more frequent and severe. In addition, rising sea levels due to climate change are expected to spread the salinity problem to a wider growing area where rice is presently cultivated under favorable conditions. The rice area in some deltas may also be affected by salinity. For example, the Mekong River delta, which accounts for nearly half of Vietnam's total rice production, is also vulnerable to sea-level rise in the future. Salinity may also spread beyond the coastal areas and deltas to some groundwater irrigation agriculture in the interior regions. The excess withdrawal could increase salinity in groundwater, making it unsuitable for rice production (Mohanty *et al.*, 2012). Similarly, drought losses would be much greater in the future, with many rainfed areas experiencing more intense and more frequent drought spells (Mohanty *et al.*, 2012).

In addition to higher production losses caused by more frequent and more severe droughts, floods, and salinity, rising temperatures will also negatively affect yield and grain quality in the future (Fitzgerald and Resurreccion, 2009). This is true if temperature becomes higher during the reproductive phase, particularly during flowering (Jagadish *et al.*, 2010). In the past three decades, nighttime minimum temperature has been rapidly rising and the current trend is expected to continue in the future. Studies by Welch *et al.* (2010) and Peng *et al.* (2004) have estimated that a 1 °C rise in nighttime temperature above critical temperature (>24 °C) would reduce yield and biomass by 10%.

Apart from direct production losses due to actual occurrence of extreme weather events and rising temperature, farmers in stress-prone environments also practice less intensive agriculture by applying less input. They end up getting lower yield, even in normal years. The rise in frequency of extreme weather due to climate change is likely to make these farmers even more risk-averse, causing further decline in yields in normal years.

Nelson *et al.* (2009) estimated the impacts of climate change on global agriculture using the IMPACT model developed by the International Food Policy Research Institute. The model includes a hydrology model and links crop simulation model to the Decision Support System for Agrotechnology Transfer (DSSAT). The study also looked at additional investments that would be required to offset the negative consequences of climate change on global food security. The results suggest that climate change will have varying impacts on rice production across regions. But the overall global rice production in 2050 under two climate scenarios (Commonwealth Scientific and Industrial Research Organisation and National Center for Atmospheric Research) is projected to decline by 12–14% relative to the 2000 level. The production effect accounts for both changes in area, yield, and farmers' adaptation due to climate change. Sub-Saharan Africa and South Asia would be the two hardest regions in terms of decline in rice production, followed by South Asia and East Asia and the Pacific. In terms of absolute change in rice production, South Asia would be the worst affected region: Rice production is projected to change from 169 million tons in 2050 under the no-climate-change scenario to slightly above 100 million tons under a climate-change scenario, a difference of more than 65 million tons of rice. The decline in production would result in higher prices and lower consumption, which eventually would lead to lower calorie intake and increase in child malnutrition. Overall, the study suggests that developing countries would be worse off than developed countries for all crops, including rice.

Similarly, a study by Agarwal (2008) estimated approximately 18% decline in Thailand's rice yield in 2020 because of climate change. Another study by Srivastava *et al.* (2009), focusing on three major rice ecosystems in India (Odisha, Kerala, and Tamil Nadu) found varying impacts of climate change on rice production. They found that in Kerala and Odisha, the decrease in yield due to rising temperature is likely to be offset by the increase in yield due to high atmospheric CO_2 concentration. However, that is not the case in Tamil Nadu, where

currently grown varieties show much greater decline in yield due to the higher temperature. It makes Tamil Nadu more vulnerable to climate change.

In addition to the above-mentioned abiotic stresses, many biotic stresses, such as pest and disease incidence and weed infestation would also be triggered by climate change. Sparks *et al.* (2012) estimated yield loss for Asia due to pest and diseases under current climate condition by combining yield loss estimates obtained by simulating a rice yield loss model 'RICEPEST' due to sheath blight, brown spot, sheath rot, bacterial leaf blight, brown planthoppers, defoliating insects, deadhearts, and whiteheads caused by stem borers, and weeds with estimates of area under two most common rice ecologies, i.e., intensive irrigated monoculture system and rainfed system. Average yield loss due to major pest and diseases was at a staggering 37% and ranged between 24% and 41%, depending on the production system. These losses would be bigger with climate change that would bring about frequent extreme weather, water scarcity, and uneven rainfall. This is particularly true for brown spot and blast, which are expected to intensify with water shortage and irregular rainfall (International Rice Research Institute). In addition, weed infestation is also predicted to rise with climate change and would represent a major challenge for sustainable rice production.

One of the most important adaptation strategies is to develop varieties that can withstand extreme weather conditions to enable them to perform better than current modern high-yielding, varieties. The future efforts should be directed in developing varieties that withstand multiple stresses such as drought and flood in the same season. This is extremely important for rainfed lowland areas where the likelihood of both flood and drought occurring in the same season is expected to be higher in the future with the changing climate.

Apart from planting stress-tolerant varieties, farmers need to modify their management practices to counter the negative effects of climate change on rice production. First and foremost, water-saving technologies, such as alternate wetting and drying, land leveling, improved tillage, bound preparation, and direct seeding, among other things, can make a significant difference in keeping the plant standing in the face of water shortage and irregular rainfall. Similarly, farmers should be educated on pest dynamics and the benefits of diverse ecosystems to keep pest at a distance in order to minimize pesticide overuse. This cannot happen without active participation of government agencies that can make policy reforms to prevent excessive use of pesticides.

Market Distortions

Historically, rice production in Asia has been subjected to extensive market distortions because of its strategic and political importance. For decades, governments in major rice-growing countries in the region have attempted to minimize market risk faced by farmers through various policy measures such as subsidized inputs (fertilizer, seed, fuel, pesticide, machinery, etc.) and guaranteed price for paddy. The goal was to support farm income and at the same time keep rice affordable for millions of urban poor. To make domestic programs work, majority of Asian countries have tried to insulate the domestic market from global uncertainty through a slew of trade measures including state trading, export ban, import ban, import tariffs, import tariffs, export quota, and others. However, since the recent rice crisis in 2007, countries have revamped their efforts to expand rice production by raising support prices at a much faster rate than what has been witnessed in the past. For example, as shown in **Figure 6**, the minimum support price (the price at which the government purchases crops from the farmers) for rice has gone up by 75% between 2007 and 2011, whereas it took 12 years, from 1994 to 2006, for the minimum support price to increase by a similar proportion.

This has resulted in a global rice market that is very small with only 5–7% of the total production as compared to 20% for wheat, 13% for maize, and 30% for soybeans. For most rice exporters in the region, trade is an afterthought when domestic need and an adequate buffer stock are achieved. However, the volume of global rice trade increased by 150% between 1990 and 2010 due to trade liberalizations by many countries in the late 1980s and the General Agreement on Tariffs and Trade in 1994 after remaining stagnant for three decades before that.

The recent rice crisis in 2007 has forced many rice-growing countries to take measures to achieve food security through self-sufficiency and move away from their dependence on imported rice. If this trend continues then the global rice market, which is already small may even get smaller in the

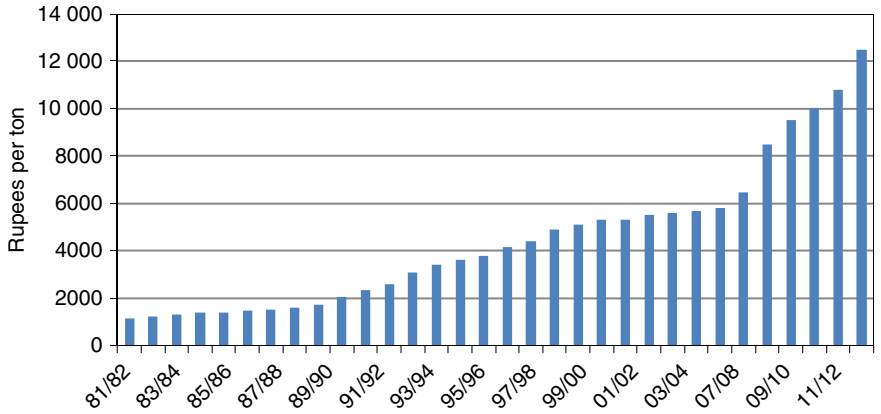

Figure 6 Indian paddy minimum support price (common varieties). Reproduced from Department of Agriculture and Cooperation, India.

future. This would push exporters such as Thailand, Vietnam, and Pakistan to cut back on their production to reduce exportable surplus and use their land for planting other profitable corps. The smaller market will lead to greater price volatility with rapid rise in rice prices in years of low production and vice versa. This will particularly affect the food security of poor countries who cannot afford to buy rice at higher prices from the international market.

Toward a Food-Secured Asia

Rice continues to remain a political commodity in Asia. Countries in the region are still bogged down with rice food security and treat it very differently from other food commodities. Despite economic boom in the region in the past three decades and rise in income and prosperity, rice consumption remains high across countries, with some diversification away from rice in a few selected countries. Interestingly, per capita rice consumption in India, China, and Indonesia, which account for more than 65% of total Asian consumption, have started rising again after steady decline in the past decade. Overall, rice consumption in Asia is projected to rise in the next two decades even with the slow down in population growth and diversification in some Asian countries.

The future supply growth, however, seems to be on shaky ground with several emerging uncertainties including possible rice area decline, slowdown in productivity growth, and climate change. The Asian rice productivity growth that has fallen below 1% in the past decade is definitely a serious matter of concern for food security in the region as further area expansion is unlikely to continue in the future. As a matter of fact, most experts feel that Asian rice area is likely to fall in the future because of population pressures, water shortage, and also competition from other crops. In addition, the ongoing structural transformation of Asian agriculture with aging farmers and out-migration of rural youths may also influence rice farming in the future. Ultimately, the onus falls on policy makers to adequately fund agricultural research and on scientists to develop technologies that are climate proof and enable farmers to grow more with less inputs and smaller environmental footprint.

Glossary

Biosecurity It is the reduction in intentional or unintentional spread of infectious disease, pathogens, or invasive pests.

Economically Motivated Adulteration (EMA) It is surreptitious addition of nonauthentic substances, unwarranted substitution of ingredients, or mislabeling of food products to gain inequitable financial advantage.

Food defense It is the reduction in the occurrence and impact of intentional acts of contamination or tampering intended to cause physical or economic harm on the food system and consumers.

Food protection The combined efforts of food safety and food defense.

Food safety It is the reduction in exposure of food to naturally occurring, unintentional hazards or failures.

Food security It is the access by all people to enough readily available, nutritionally adequate, and safe food for an active, healthy life. This includes the ability to acquire acceptable foods in a socially acceptable way.

Food terrorism The deliberate (or threat of) contamination of food with hazardous agents (biological, chemical, physical, or radionuclear) for the purpose of causing injury or death and/or disrupting social, economic, or political stability.

Introduction

Food safety programs focus on reducing unintentional contamination of the food system, whereas food defense programs are designed to reduce intentional contamination of the food system. A common goal for both food safety and food defense programs is to prevent foodborne illness; however, "foodborne illness from intentional contamination results not from system failure (as in food safety), but instead from intentional attacks on a system that defeat the in-place controls" (Kennedy and Busta, 2013, p. 93). The unique challenge of food defense is that the adversaries are not just pathogens routinely finding niches to survive and grow along the food processing chain but can also be intelligent humans with the ability to craft a method that will evade detection and will overcome control systems in order to deliver a deleterious agent to consumers. Therefore, food safety systems such as Hazard Analysis and Critical Control Points (HACCP) are a start, and only a start, to a well-defended food system.

Motivations for an individual or group to contaminate the food system may include extortion, political assassination or coercion, a disgruntled employee, interpersonal conflict, or to use food as a means of terrorism. Food terrorism is the intentional contamination of food to harm people, animals or plants, or otherwise create terror, panic, or economic disruption. However, food terrorism is distinguished from nations attacking other nations. Food terrorism is generally attributed to nonnation actors attempting to disrupt the stability of a nation or the food supply (World Health Organization, 2008).

Food defense contributes to the overarching goal of food security: the accessibility of adequate nutrition to support a healthy, active lifestyle and the ability to obtain that nutrition through socially acceptable means, that is, food security cannot be achieved without the food being safe from intentional contamination. See **Figure 1** for relationships between the various food system programs.

The first step in creating a food defense plan is risk assessment. The goal of risk assessment is to identify the highest hazard and most likely vulnerabilities to be exploited in a food defense incident. The analysis informs how resources can be used commensurately to the vulnerabilities, addressing highest priority vulnerabilities first. Intentional contamination of food could involve sundry biological, chemical, physical, or radiological threat agents. There were more than 350 confirmed malicious contamination of food from 1950 to 2008, and there have been 169 separate recorded incidents of economically motivated adulteration (EMA) around the world since 1980. Examples of each type of incident are highlighted here in the following sections.

Before, during, and after a food defense incident, best practices must be used to design effective risk and crisis communication messages to the public. Risk and crisis communication could mean the difference between public outrage and public collaboration when addressing a food defense incident. The most recent, most impactful official policies on food defense include the Food Safety Modernization Act (FSMA), US Presidential Policy Directive 8 (PPD-8), and the International Health Regulations (IHRs). Official policy serves as a driving force to develop food defense systems in the food supply.

The importance of food defense is evident by its potential for catastrophe: "Intentional contamination of the food system has the potential to result in disastrous and far-reaching effects, including direct morbidity and/or mortality, disruption of food distribution, loss of consumer confidence in government and the food supply, business failures, trade restrictions, and dramatic ripple effects on the economy" (Busta and Kennedy, 2011, p. 120). The fact that the food system is an extraordinarily complex network of supply chains creates a twofold challenge: there are many points along the supply chain that could be contaminated, and it is exceedingly difficult to monitor and protect every step and transfer. Globalization of the food system adds greatly to this challenge

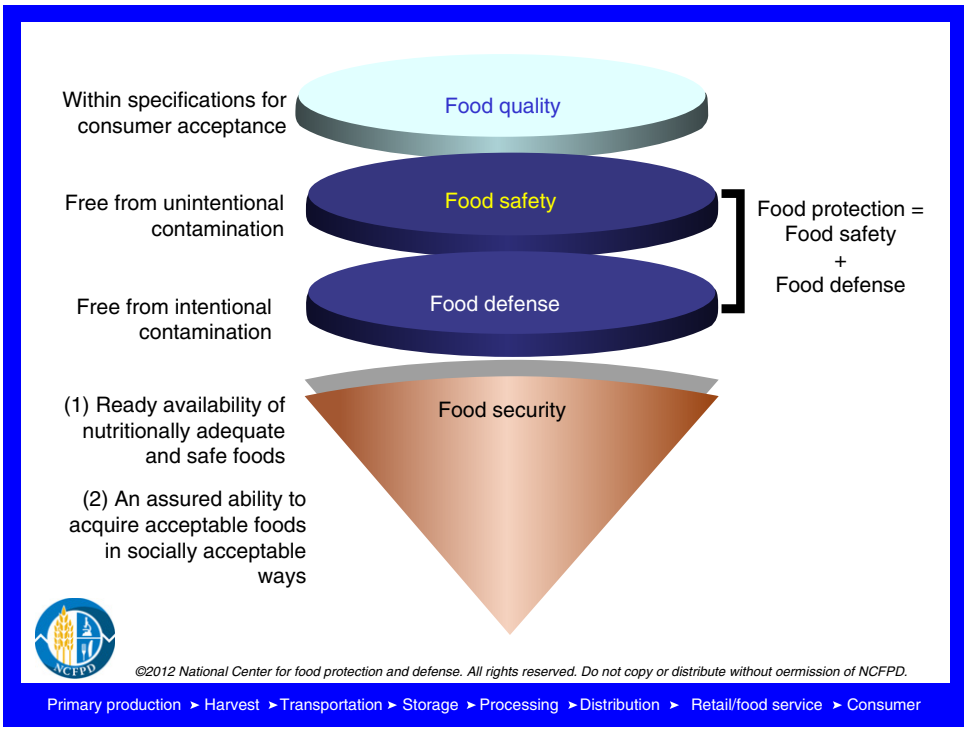

Figure 1 Relationships between food system programs. Reproduced with permission from Figure 7.1 in Busta, F.F., Kennedy, S.P., 2011. Defending the safety of the global food system from intentional contamination in a changing market. In: Hefnaway, M. (Ed.), Advances in Food Protection, NATO Science for Peace and Security Series A: Chemistry and Biology 1. Dordrecht, The Netherlands: Springer Science & Business Media B.V., p. 121.

because vulnerability existing in one nation traces into another nation through trade. The entire farm-to-table food system must invest in infrastructure to prevent, rapidly identify, and respond to intentional contamination or threatened intentional contamination; moreover, transnational collaboration is essential for complete food system defense.

Global Food System Defense

Today's food system is a vast and incredibly complicated network of supply chains. Each supply chain is also an elaborate concert of producers, processors, suppliers and buyers, exporters and importers, and retailers and distributors. The food system is literally complexity compounded on complexity which creates a problem in the realm of food defense: "The transition of the agriculture sectors in the developing world from subsistence agriculture to agribusiness... directed at commodity and value-added exports has dramatically increased access to the food supply chain and consequently increased vulnerabilities" (Busta and Kennedy, 2011, p. 124). Specifically, vulnerabilities arise when food products are created from disparate global sources as well as when they are produced and distributed rapidly and widely.

Given the magnitude and interconnectedness of the modern global food trade, "an attack on one country's food supply cannot be seen in isolation" (World Health Organization, 2008, p. 11), and the contamination may spread to other countries through trade. For example, staphylococcal toxin contamination in canned mushrooms from China caused illness in the US in 1989 (World Health Organization, 2008). Therefore, the World Health Organization (WHO) explains that thorough collaborative relationships between nations are imperative for global food defense: "cross collaboration with governments, global cooperation in surveillance and outbreak preparedness, alert and response, open sharing of knowledge, technology and materials and capacity building in health security is necessary by Member States" (World Health Organization, 2008, p. 3). Since the 55th World Health Assembly in 2002, WHO has worked to provide tools and support for Member States to prepare for and respond to food defense threats. The role of the WHO in a food terrorism event is to act as the directing coordinating agency, implementing the IHR and assisting in other varied emergency response action capacities.

A bioterrorism incident in the food system would also have enormous economic impact on the food industry domestically and internationally. In 1998, a company in the US recalled 14 million kilograms (30.9 million pounds) of sausages, frankfurters, and luncheon meats potentially contaminated with *Listeria*. The company closed the plant and estimated their total loss to be US$50–70 million (€38–54 million) (World Health Organization, 2008). This example is a demonstration of the vast economic impact of contamination in the food supply. The losses are exacerbated when such an incident causes nations to bar trade from the nation experiencing the contamination. The UK 's multiyear Bovine Spongiform Encephalopathy (BSE) crisis caused an estimated loss between £740 and £980 millions (€0.8–1.1 billion, US$1.1–1.5 billion) in 1 year alone. The crisis also caused the European Union and other countries to ban the export of British beef,

and once the suspected link between BSE and variant Creutzfeldt–Jakob Disease was announced, public confidence in the beef industry and the government was greatly diminished (Atkinson, 1999).

Closing borders as a response to a global food defense incident is perhaps too little, too late – the food system is too globalized, and products move too rapidly for that to be an effective response to prevent the movement of contaminated food. The systems necessary to prevent and efficiently respond to an international food defense incident are not yet in place, and many countries may not have the public health service capacity to effectively address the illnesses resulting from a catastrophic food defense incident. Food defense as a threat to public health is not theoretical. There have been real cases of intentional contamination of the food supply to cause harm to public health. For these reasons, international collaboration is needed to improve global food defense.

Highlighted Food Defense Incidents

Biological warfare dates back to ancient history and is still timely today. One of the earliest records of intentional contamination of a food or water supply is when the Athenians contaminated the city of Kirrha's drinking water circa 600 BC to lay siege to the city easier while its citizens suffered from gastroenteritis. In more recent history, Japan experimented during World War II with food as a vehicle for pathogens (Kennedy and Busta, 2013). The difference between warfare and food defense is that warfare involves one nation versus another nation, but malevolent nonstate actors working to disrupt order or cause physical harm carry out food defense incidents.

Intentional contamination incidents have been recorded at every major point along the farm-to-fork continuum: preharvest, processing, transportation, retail, and consumer levels. Figure 2 shows a map of the more than 350 confirmed malicious contaminations of food by different countries from 1950 to 2008. There is a difference between intentional contamination to cause harm to an individual or group of people (malicious contamination) and intentional contamination for economic gain (EMA), but both cases may lead to catastrophe. For example, 20 000 injuries and 800 fatalities in 1981 were the result of 'toxic oil syndrome' from EMA of cooking oil with industrial rapeseed oil in Spain (Dalziel, 2009). This example is one of many alarming instances that show just how easy it is to contaminate the food system despite

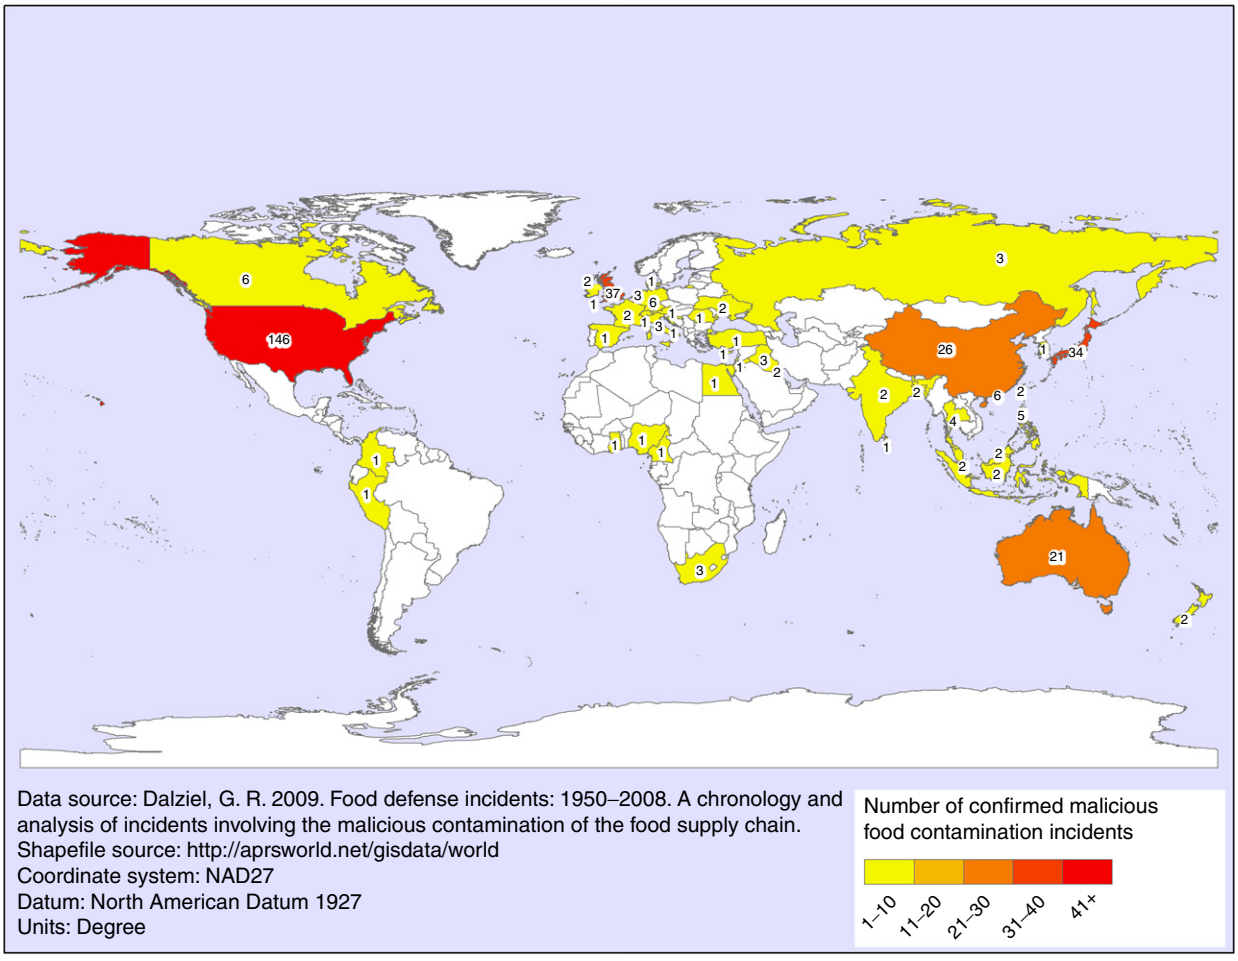

Figure 2 Confirmed malicious contaminations of food around the world.

the food safety and quality systems in place. If contamination can occur at a large scale for unfair economic gain, it can also occur just as easily as a malicious attack, so food defense systems should be in place to reduce that vulnerability. EMA is discussed more in the Section Economically Motivated Adulteration. There is also a difference between contaminating foodstuffs with deleterious agents and destroying or vandalizing food industry infrastructure (buildings, crops, shipping vehicles, etc.). Vandalism on food system infrastructure is not discussed here. Other motivations to contaminate the food supply include extortion, political assassination or coercion, a disgruntled employee, interpersonal conflict, or to use food as a means of terrorism. Extortion incidents are typically underreported by law enforcement in order to minimize copycat incidents and damage to consumer confidence in the food system (Dalziel, 2009).

There have been seven cases of water supply contamination from 1950 to 2008. These incidents caused a total of three fatalities and fewer than 100 other injuries. Most water supply incidents involve pesticides and insecticides with limited toxicity. Given the comparatively few events and small impact, it could be concluded that widespread hazard of intentional water supply contamination is unlikely (Dalziel, 2009).

Preharvest contamination events have also been relatively rare. Pesticide was once used to contaminate the tank of a crop duster in Australia; the contaminated food was brought to market, but a subsequent recall was issued, so the incident resulted in no injuries or fatalities. Incidents that resulted in harming animals or crops that never made it to market are more common. In 1970, the water supply for a cattle farm was contaminated with cyanide, killing 30 cattle in AL, USA, and 500 000 fish were killed when a Northern Ireland fishery was contaminated in 2001. The economic effects of events at this point in the food chain are the preponderant result rather than human health consequences. A famous historical example is when Chilean grapes were allegedly found to have trace levels of cyanide in 1989. The resulting trade bans caused US$300 million (€232 million) in losses. However, laboratory results were disputed, so this instance serves as a demonstration of the impact public perception can have in the event of potential food contamination and the importance of good risk and crisis communication (Dalziel, 2009).

A total of three incidents have been confirmed during assembly, processing, packaging, or storage. When combined, the incidents resulted in 125 injuries but no fatalities. The largest incident occurred in China. A total of 120 citizens fell ill from eating noodles that had been contaminated with rat poison at the factory. At the time, the factory was undergoing a property–leasing dispute (Dalziel, 2009). This example shows the importance of fostering a food defense culture at processing plants to help protect the food system from contamination, especially during times of disorder.

With a wide variety of agents used (e.g., arsenic, *Salmonella typhimurium*, pesticide, etc.), 85 instances of contamination have been confirmed occurring at the retail and food service level of the food system. These incidents resulted in 123 deaths and 3304 other injuries during 1950–2008 (Dalziel, 2009). Incidents at this part of the food supply chain caused the heaviest casualties with an average of 40 casualties (fatalities plus injuries) per incident. The most famous case is when the Rajneeshee clan contaminated salad bars in Oregon with *Salmonella typhimurium* in 1984. The final illness count was 751, 45 of whom were hospitalized (Dalziel, 2009; Török *et al.*, 1997). This incident is the only "instance in which a terrorist group operating in the US employed a chemical or biological weapon" to contaminate the food system (Carus, 1998, p. 7 cited in Dalziel, 2009, p. 19). Another widespread incident occurred in 1992 when flour at the College of Finance and Taxation cafeteria in Zhengzhou, China was contaminated with arsenic, resulting in 788 illnesses (Dalziel, 2009).

The majority of intentional contamination incidents happened at the consumer and home level of the food system. There have been 263 cases of intentional contamination causing 265 fatalities and 670 other injuries or illnesses. Although most cases happen at this level, the large majority (70%) of these cases caused only 1–4 casualties per case (Dalziel, 2009). The challenges of preventing and detecting incidents at this level are that each incident usually affects only a few people, and without detection systems at the consumer level other than organoleptic detection, many incidents could go unnoticed until the adverse effects take place. This is especially true for chemical or biological agents that create no noticeable organoleptic effects in the food. The incidents at this level often involve household cleaners and chemicals or readily available pharmaceuticals making threat agent control especially challenging.

Only nine out of all the confirmed incidents during 1950–2008 involved biological agents such as pathogenic microorganisms, toxic plant matter, and fecal matter (Dalziel, 2009). Radiological agents (e.g., phosphorus-32, iodine-125, and polonium-210) were used in only 8 of the incidents. Radiological agents account for a single fatality and 36 injuries. The single fatality was the 2006 poisoning of Soviet KGB officer and spy, Alexander Litvinenko, with polonium-210 allegedly placed in food at a restaurant. A common thread between the radiological and biological agents is that several cases in each category involved an adversary that worked in a laboratory setting and had direct access to the agents. The remainder of the recorded incidents involved chemical agents – mostly chemicals that are readily available to the public.

In summation, 98% of confirmed intentional contamination incidents occurred late in the food supply chain (e.g., consumer and retail), but incidents earlier in the food chain have much larger impact per event. There have been 391 deaths and 4355 illnesses from malicious food contamination during 1950–2008 (Dalziel, 2009). Nonmalicious contamination of the food system is also a common occurrence. These events are called EMA.

Economically Motivated Adulteration

EMA is substituting or diluting foodstuffs with lesser value ingredients, mislabeling food, counterfeiting, or otherwise masking the true origin or quality of a food in order to unfairly gain access to a market or to obtain a higher price for the food than it is worth. As opposed to intentional contamination for bioterrorism, EMA is executed with the intention of never being discovered. The intention for a malicious adversary is to

Table 1 Potential food defense threat agents

Threat agent	*Oral lethal dose (LD_{50})*
Abrin	0.04 μg kg^{-1} in mice[a]
Bacillus anthracis	$>10^8$ spores in rabbits[b]
Botulinum neurotoxin	0.001 μg kg^{-1} in mice[a]
Clostridium perfringens epsilon toxin	0.1–5.0 μg kg^{-1} in mice[a]
Cyanide	30 μg kg^{-1} in rats[c]
Fluoroacetic acid	5 μg kg^{-1} in rats, 7 μg kg^{-1} in mice[d]
Ricin	3–5 μg kg^{-1} in mice[a]
Saxitoxin	263 μg kg^{-1} in mice[d]
Shiga-toxin producing *Escherichia coli*	0.002 μg kg^{-1} in mice[a]
Staphylococcal enterotoxin	1–25 μg kg^{-1} in humans[e]
Strychnine	2350 μg kg^{-1} in rates, 20 μg kg^{-1} mice[d]

Table 2 Incidents of economically motivated adulteration (EMA) in food since 1980

Food category adulterated	*Number of incidents recorded*
Fish and Seafood	66
Dairy	14
Alcoholic beverages	13
Oils and fats	11
Grains and grain products	11[a]
Spices and extracts	9
Fruit juices and concentrates	8
Meat and meat products	8
Produce	7[a]
Honey and other natural sweeteners	6
Eggs (duck and chicken)	5
Other	4
Coffee and tea	3
Infant formula	3
Other beverages (soft drinks)	2

[a]One incident included adulteration of both produce and grains products.
Source: National Center for Food Protection and Defense (NCFPD), 2012a. NCFPD EMA Incidents Database. Saint Paul, MN: National Center for Food Protection and Defense. Available at: https://www.foodshield.org/ (accessed 28.03.13).

cause harm and disruption, and the actor wants the act to be recognized as terrorism rather than a routine foodborne illness outbreak. However, fraudulent food producers do not want to be discovered, so they may continue selling their adulterated product as long as possible. Global trade has created uniquely multilateral opportunities for EMA: transshipment to avoid duties or specific embargoes or port shopping to find a port that will accept previously rejected food or avoid inspections (Busta and Kennedy, 2011). Incidents of EMA demonstrate times when regulatory and quality controls currently in place in the food system were evaded. If the controls can be evaded for economic gain, then they may be evaded for bioterrorism too (**Table 1**).

If the fraudulent food itself or the adulterant added causes unintended health consequences in consumers, the resulting health effects are often the trigger to signal an intentional contamination incident. For example, toxic oil syndrome in Spain in 1981 and melamine contamination in Chinese milk and wheat gluten during 2006–08 were all instances of EMA that were discovered only after the catastrophic public health consequences. There have been 169 separate recorded incidents of EMA around the world since 1980 (NCFPD, 2012a). These incidents are summarized in **Table 2**, organized by what category of food was adulterated.

According to the NCFPD (2012a), the most often adulterated category is fish and seafood. The seafood supply chain includes many producers and complicated handling transfers, and after the fish has been disassembled, it is very difficult to identify. Those combined factors make fish and seafood particularly vulnerable to mislabeling. For example, a restaurant or seafood retailer may list red snapper, grouper, or flounder, but the consumer may not notice that the fish that is served is actually a different (and often of lesser value) fish such as tilapia, cod, or swai. Many cases of seafood mislabeling are not dangerous to public health, so the major concern is that consumers are being deceived and overcharged for low-value fish and seafood. However, there are some cases where substitution or mislabeling of fish may cause harm. For example, the Food and Drug Administration (FDA) warns against consuming the fishes escolar and oilfish: "In some people, eating even small amounts of these fish can cause oily diarrhea... abdominal cramps, nausea, vomiting and headache" (Fry Jr., 2012, p. 220). There have been two confirmed incidents when escolar was served instead of the white fish named on the menu (NCFPD, 2012a).

The second most adulterated food category for unfair economic gain is the dairy. The most relevant and impactful example occurred in China between 2007 and 2008. Milk was contaminated with melamine, a toxic industrial chemical, to increase the nitrogen content of the milk. The protein content of milk is determined by the total nitrogen content, using the Kjeldahl method (FDA, 2011). Melamine is high in nitrogen, so adding melamine to the milk artificially increased the protein content analysis readout. The consequences of this EMA were disastrous: 300 000 illnesses and 6 infant deaths from kidney complications (Gossner *et al.*, 2009; NCFPD, 2012a).

In addition to the potential for negative health consequences, EMA is a concern for profitability of honest food production firms. It has been estimated that EMA and counterfeiting costs the food industry US$10–15 billion (€7.7–11.6 billion) per year (GMA and A.T. Kearney, 2010). It is agreed that this complex of a problem will require collaboration between industry partners and the government. Some industry-wide solutions to EMA have been proposed: an information-sharing clearinghouse to disseminate EMA-related information to the industry, a shared audit program and ingredient analysis library to reduce costs, and relationship building for sharing information through trade associations (GMA and A.T. Kearney, 2010). A database of the susceptibility of food ingredients to EMA has been published (NCFPD, 2012b; Moore *et al.*, 2012) to help spread information about

the susceptibility of common food ingredients to EMA. Given the occurrence of intentional contamination, malicious and not, there have been new official policies written to address this problem.

Food Defense Policy

Strengthening food defense programs around the world requires national policies and resources to support food defense infrastructure. The role of food defense policy is to ensure that food monitoring and surveillance, inspection, foodborne disease surveillance, education and training, and food handlers' food defense plans are adequate and up to date. Much of the officially adopted policy with explicit or implicit language on food defense has been written in the US, but the topic of food defense policy is growing in popularity around the world. Intergovernmental organizations such as the WHO have written guidelines and recommendations to improve food defense globally.

In response to the terrorist attack on the World Trade Centers on 11 September 2001, the US passed the Public Health Security and Bioterrorism Preparedness and Response Act of 2002 (aka The Bioterrorism Act of 2002). Title III of the act is entitled 'Protecting Safety and Security of Food and Drug Supply,' and it describes the actions that the US government and food system will take to ensure that the food and drug supply is protected from bioterrorism (107th US Congress, 2002). To implement this act, the US FDA requires that all food facilities be registered with the FDA and that all importers shipping food to the US must give the FDA 24 h advance notice of their arrival to a port of entry (see list of relevant web pages for more information).

In 2004, George W. Bush's Homeland Security Presidential Directive 9 (HSPD-9) called for the establishment of university-based centers of excellence to address various homeland security challenges (Bush, 2004). The food system was one of the critical infrastructures identified and many university consortia competed to be selected as a center of excellence. In June of 2004, a consortium led by the University of Minnesota was identified as the winner of the competition, and the National Center for Food Protection and Defense (NCFPD) was established. NCFPD is still highly active today pursuing its vision: "defending the safety of the food system through research and education." See the list of relevant websites for NCFPD's homepage URL.

In FDA's 2007 Food Protection Plan, the FDA requested authority to require mandatory controls in the food system for both unintentional and intentional contamination. This request came to fruition when the US FSMA passed in 2011 (see list of relevant web pages for more information). The FSMA requires organizations to "identify and evaluate hazards that may be intentionally introduced, including by acts of terrorism" (111th US Congress, 2011, Section 103(b)(B)(2)). Although this law was passed in 2011, regulations are still being written.

US President Barack Obama's PPD-8 describes a vision for a national preparedness goal for the US at large, and critical infrastructure like the food system are topics affected by this directive. Interpolated from the overarching language in PPD-8, there are 5 frameworks of planning for food defense: prevent, protect, mitigate, respond, and recover. The plans for each framework should be designed to coordinate with each other in order to create a fluid preparedness system.

- *Prevent*: The capability to avoid or stop an intentional contamination event from happening in the first place. Prevention capabilities for the food system include information-sharing environments and employee screening.
- *Protect*: The capability to halt an intentional contamination event that is underway. This includes fostering a food defense culture so that individuals keep a watchful eye on activity at their certain part of the food system. More technical capabilities include locks on food containers and trucks, limited access to production floors, and fences and surveillance at the proximity of sensitive nodes in the food chain.
- *Mitigate*: The capability to reduce morbidity, mortality, and economic loss after an incident occurs. In the food system, mitigation strategies include rapid threat agent detection, recall procedures, and high-quality crisis communication.
- *Respond*: Response capabilities include emergency management systems, healthcare systems, and recalls to save lives after an incident has occurred.
- *Recover*: Recovery capability of the food system involves regaining market access, public trust, and business continuity of the food products that were contaminated in the food defense incident (Obama, 2011).

Around the world, government has many roles in fostering food defense for a nation. Overall, the role of government is to oversee the food system from a broad perspective so that the producers can put their focus on the quality of their production. The government should collaborate with the food industry to perform risk assessment, create response and recovery plans, and ensure that preventive controls are in place. The government also has a role with the general public, especially in risk and crisis communication. See Section Risk and Crisis Communication for more on that topic.

The WHO IHR have a role in establishing food defense practices around the world. The Regulations are a framework for international public health surveillance, assessment, and response for the WHO and its member states (World Health Organization, 2008). The purpose of these international policies is to prevent and respond to public health risks that could cross borders. As discussed above in the Section Global Food System Defense, a food defense incident could easily spread to other nations due to the vast international trade network that characterizes today's globalized food system (World Health Organization, 2013). The State Parties that decide to abide by the IHR must create a centralized authority for communicating and guiding the implementation of the IHR, follow reporting protocols, and complete assessments all for the goal of improving international public health (World Health Organization, 2013). See the list of relevant web pages for more information.

Threat Agents and Detection

Threat Agents

There are four general classes of threat agents that could be used to maliciously contaminate foodstuffs: biological, chemical,

physical, and radiological. Biological agents include infectious pathogenic bacteria, viruses, or parasites. Chemical agents of concern include man-made or natural toxins, industrial cleaning agents or lubricants, pesticides, allergens, etc. Agents used for EMA mostly fall under the chemical (either toxic or nontoxic) and physical classes. EMA is not intended to harm the consumer, but the agent used may cause unintended harm. The history of food defense incidents show that chemical agents are the most common adulterant probably because of their availability: "the most commonly used compounds for poisoning were those that were either at hand or readily available on the market" (Dalziel, 2009, p. 6). Another reason that chemical agents are the culprit most often is because 100 or more years of food safety and food quality program development, research, and regulation have focused on controlling microorganisms (especially pathogens) rather than chemical agents. Toxins extracted from biological sources (e.g., ricin and Shiga toxin) are the intersection of the biological and chemical categories. Physical agents include glass, needles, metal shards, etc. Fortunately, many food manufacturing lines not only include magnetic or X-ray detectors originally included in the food safety program but also serve food defense goals. Radioactive chemicals are also a concern because of their availability in research laboratories and their heightened hazard when ingested. The Centers for Disease Control (CDC) and Prevention National Select Agent Registry shows agents that are of particular biosecurity concern because of their potential for high mortality (see list of relevant web pages). An additional hazard that characterizes the agents on this list is that many physicians are not familiar with diagnosing them, so accurately identifying the problem may be severely delayed in a food defense incident. **Table 1** lists highlighted food defense threat agents and their oral lethal doses.

A key to threat agent analysis is the understanding that the context (e.g., delivery method, heat stability, lethal or infectious dose, availability of the agent, etc.) in which a certain agent is most hazardous can help in determining which agents are of greatest concern for certain parts of the food system. Current research explores the reaction kinetics and viability of threat agents in certain food matrix contexts (Lumor *et al.*, 2012; He *et al.*, 2011). To be a threat, an agent must be stable in the particular food matrix and must survive the control steps (thermal treatment, washing, etc.) it will undergo. To cause harm to the consumer, a toxin will have to outlast inactivation, and microorganisms may have to survive in great enough numbers to be infectious. If an agent produces noticeable organoleptic changes (e.g., turbidity, color change, and off-odors and flavors), the public may not consume the contaminated food, and illness may be prevented. Understanding the contextual toxicity of threat agents in food matrices will inform risk assessment decisions and prioritize countermeasure implementation.

Pasteurization kinetics can be used to the advantage of food defense. Increasing the total heating schedule will help to control certain microbial and toxic contaminants. Certainly, if the agent was particularly heat resistant (e.g., Bacillus anthracis spores), the organoleptic effects of additional thermal processing needed would make the product unacceptable to consumers. Some nonthermal processing methods are now also effective at delivering 5 log cycle microbial population reductions such as high-pressure processing and ionizing radiation (Kennedy and Busta, 2013).

Detection

There are three general methodologies for detecting a food defense incident in the food system: detect to prevent, protect, and recover. Detect to prevent means detecting the contamination before the food leaves the facility. This method prevents any chance of public health consequences, but the food producer incurs all costs of testing and detection. Detect to protect means detecting contamination of the food after processing but before sale to the final consumer, so all public health impact is again avoided. This is the method intended during a recall, and this method is even more expensive for the production firm because it has already paid for the food to be moved down the supply chain. There may also be indirect losses from a drop in consumer confidence in the brand during and after a recall. Detect to recover (or detect to mitigate) means the contamination was not identified before consumption of the food, and now the deleterious product must be removed from the supply chain and retrieved from consumers as quickly as possible to limit the public health impact (Kennedy and Busta, 2013).

Currently, it is most likely that detection of a food defense incident would be based on illness data due to the contaminated food – a detect to recover method. However, this is a difficult task because it can be analogous to finding a needle in a haystack: "The main requirement for rapid detection of an epidemic is a surveillance system that is sensitive enough to identify small clusters of illness" (World Health Organization, 2008, p. 20). Surveillance systems that detect contamination incidents based on cases of foodborne illness are passive systems, relying on reporting from physicians and laboratories to detect outbreaks. The disadvantage of this method is that it is not proactively searching for contaminated food, and there is a delay from the time of contamination to the time of consumption up to several days, that is, enough time for the food to be widely distributed and consumed, especially if the food has short shelf life and is consumed quickly after purchase (e.g., milk and produce). A key factor for the magnitude of public health impact from an intentional contamination incident is the speed of distribution and consumption after processing. A food that is distributed and consumed quickly would have more intense public health effect if it were contaminated than a food that is held at a location before reaching the consumer. There is a better chance that in the latter case the food would be recalled before consumers ate it.

Some existing surveillance and detection systems are FoodNet, C-EnterNet, OzFoodNet, and PulseNet. The CDC and Prevention's FoodNet, the Public Health Agency of Canada's (PHAC) C-EnterNet, and the Australian Government Department of Health and Ageing's OzFoodNet are consortia of sentinel site clinical laboratories that track and disseminate information on instances of illness for select foodborne pathogens. PulseNet, also CDC-coordinated, is a collaborative database and sharing environment of pathogenic bacteria's 'fingerprints' based on pulsed-field gel electrophoresis (see list of relevant web pages for more information on each of these systems). Detection at the laboratory requires the laboratory to have the necessary test on hand and the ability to interpret the results. Communication lines between laboratories and

emergency managers must be efficient for rapid response. Many countries, however, do not maintain a surveillance system that detects foodborne illnesses, so the event may go undetected for even longer. New opportunities for food defense surveillance include mining other sources of information that are potentially indicative of a foodborne disease outbreak: unusually high demand at pharmacies for certain drugs, veterinary surveillance systems, consumer complaint hotlines in the food industry, unusual coroner's reports, and mass absentees in large facilities.

Innovations in detection methods for nefarious biological or chemical agents are being developed in laboratories around the world. Methods in development include Raman spectroscopy, nanoparticles, immunoassays, biological cell bioassays, and more (Kennedy and Busta, 2013). Laboratory detection methods may be expensive, so vulnerability assessment is useful to determine which methods and other interventions are the highest priorities.

Vulnerability Assessment

The purpose of food defense vulnerability assessment is to identify and weigh the hazard and likeliness (risk) of particular intentional contamination incidents at a food processing facility or along an entire supply chain. The end goal of the analysis is to commensurately allocate resources to achieve the highest level of security for the resources available. The challenge is in finding which nodes in the system are the highest priorities to protect and if the chosen intervention is fiscally justified. Terrorism scholar Brian Michael Jenkins writes, "the danger arises when speculation becomes the basis for launching costly efforts to prevent 'what ifs'" (Lesser *et al.*, 1999, p. xi).

The food system may be contaminated at any of many points in the complex network of supply chains. Risk assessment involves identifying the agents that could be used and the places the agents could be introduced in a food chain. Some supply chains may be more susceptible to certain agents at certain points than others. Therefore, one role of risk assessment is to elucidate which agents and nodes are of particular concern for a certain supply chain. Case-by-case assessment is necessary to understand the unique risk profile for each part of the food system.

Food production firms are responsible for evaluating any work process that could be vulnerable to a food defense incident. Certainly, that includes the manufacturing floor, but the facility utilities (water, air, etc.) should also be included in the assessment (Biegel and Beach, 2010). Similar to hazard analysis for HACCP, the first goal of vulnerability assessment is to identify potential hazards and points of entry for intentional contamination. For each hazard and at each entry point, a judgment is made on the level of risk and the level of hazard. Hazard is the degree to which the event can do harm, and risk is the probability of the particular vulnerability being exploited. Highest hazard and risk vulnerabilities should be addressed foremost.

Determining the hazard of a potential food defense event is particularly challenging and unfortunately subjective. One method is to judge the potential impact of an intentional contamination incident based on the impact from unintentional contamination events in the past. Some key events have caused hundreds of thousands of illnesses. For example, unintentionally contaminated clams in China caused 300 000 hepatitis cases in 1989 (Manning *et al.*, 2005 cited in Dalziel, 2009). The contrary theory says that comparing the potential hazard of intentional contamination with actual reports of unintentional events is spurious because it does not take into account an adversary's ability to orchestrate the attack to evade systems in place designed for food safety. The impact of a designed attack with a carefully chosen agent could be catastrophic, but such events have been very rare. Therefore, foolproof risk assessment is not possible without actual events to base the claims on stochastic statistics. Considering centralized food processing, wide distribution, and that aggressive pathogens and high toxicity agents exist, there is potential (although rarely realized) for incidents even more hazardous than food safety incidents from the past.

The severity of a threat agent is determined by: (1) public health impact potential for delivery to a large population through the food system, (2) availability of the agent or possibility of its production, (3) interpersonal transmissibility of the agent, (4) public perception of the agent (an agent may be chosen because of its shock factor), (5) healthcare system's response capacity (e.g., antiserum stockpiling), and (6) difficulty of detection before consumption. In the US, the Department of Homeland Security biennially performs the Biological Terrorism Risk Assessment and the Chemical Terrorism Risk Assessment considering "aggressor intent and capabilities, ease of agent acquisition, ease of agent introduction, probability of agent survival through to target populations and probable public health (primarily) consequences" (Kennedy and Busta, 2013, p. 100).

Based on historical evidence, the closer the food gets to the consumer, the higher is the risk of intentional contamination. (Dalziel, 2009). However, the hazard for large-scale health impact is highest at the centralized points in the supply chain where large amounts of food may be contaminated all at once and then widely distributed. Perhaps the greatest risk of intentional contamination are the scenarios that the food industry sees as so unlikely that they do not need to invest in controlling them. It is in these unexpected blind spots in security that a malicious attack could take the industry by surprise.

Compared with the occurrence of food safety incidents at the processing plant level, food defense incidents are very rare. Because there are no routine food defense incidents like there are food safety incidents, food manufacturers are understandably not as motivated to invest in preventive methods specifically for food defense, that is, the return on investment for food defense infrastructure is more difficult to rationalize than the return on investment for food safety precautions. Furthermore, food safety programs are required by policy, but food defense programs are not yet.

Developed by the US National Air and Space Agency and Department of Defense, the US FDA has adopted Operational Risk Management for some risk assessment tasks. The method follows a typical hazard analysis process: Risks are identified and assessed for their relative hazard level, and

then interventions specific for each risk are identified and implemented. The final step is to assess the success of the intervention made. After interventions are implemented, the risk assessment process is reiterated to achieve acceptable levels of vulnerability. Each vulnerability is assessed on the basis of the intensity of the hazard it poses and on the probability that it may be exploited. The highest hazard and highest risk vulnerabilities are the top priority for intervention. For food defense, the severity of a hazard is relatively well understood compared with the probability of the hazard; large-scale intentional contamination events resulting in public harm are not common enough for sound statistics to be performed under the assumption that these events are stochastic.

Another risk assessment tool currently used is CARVER +Shock. This method assesses risk in a system based on seven elements. The initial letter of each element makes up the acronym 'CARVER,' and 'Shock' includes psychological or other hazards. The US Department of Agriculture and the FDA use 10-point scales to rate a node in the food system on each of these elements. Higher scores mean greater vulnerability or hazard (see list of relevant web pages for more). The seven elements are:

- *Criticality*: The degree of public health or economic consequence.
- *Accessibility*: Ability of the perpetrator to gain access and egress from the point of contamination.
- *Recuperability*: The delay required to bring the system back into operation. Higher scores mean longer recovery times.
- *Vulnerability*: The potential for a successful attack. In the food system, this means the ability to introduce enough of a deleterious agent to cause harm and for the agent to survive control steps to reach the consumer.
- *Effect*: Direct loss from the attack as measured by lost production of that product in the food system.
- *Recognizability*: Ease of target identification by an adversary.
- *Shock*: The combined health, economic, and psychological impacts of the attack. Economic and psychological impacts of an attack may not cause morbidity or mortality, but they may result in substantial loss of public confidence in the food system or the government (Kennedy and Busta, 2013; Catlin and Kautter, 2007).

The first task of a CARVER+Shock analysis is to identify the nodes of a given processing plan. Each node represents a change in the vulnerability of the system to contamination. When combined, the nodes represent the entirety of the process under examination. For example, each unit operation (receiving, mixing, thermal processing, etc.) and every transfer between unit operations in a food processing facility count as nodes. Next, each node is evaluated on each of the seven CARVER+Shock elements. The sum of the element scores for each node is used to identify which nodes are most vulnerable. One limitation of this method is that if many parts of a diverse system are compared, the method becomes less valid to quantitatively compare the node scores. Therefore, extrapolation of this method to cover an entire supply chain may not result in a valid vulnerability assessment. More information on CARVER+Shock can be found on the FDA's web page named below in the list of relevant web pages.

Food Defense Preparedness

A critical design aspect of a successful food defense plan is that is has redundant protection: "The goal of the Food Defense Plan is to implement procedures in layers, like that of an onion, so that each time a layer of defense is peeled back there is another layer in place to discourage or prevent an incident from occurring" (Biegel and Beach, 2010, p. 12). Ideally, there would be layers of defense at every node along the food supply chain. A similar metaphor is the hurdle philosophy in food safety: a pathogen may be able to survive and grow when one aspect of the food environment is unfavorable, but the probability of the pathogen's success diminishes with the number of hurdles. For example, the pathogen may be able to grow in low pH, but it would be unable to grow in low pH plus high salinity. By the same token, an adversary may successfully design a way for his/her contamination to survive the thermal processing step, but he/she may not be able to also overcome key card-restricted access to the processing floor.

Creating a food defense plan and implementing security interventions follows directly after the risk assessment process. Resources to implement mitigation strategies and preventive methods should be allocated commensurately to the severity and likelihood of the vulnerabilities found, that is, the highest hazard and the highest risk vulnerabilities deserve the foremost intervention to protect, and lesser vulnerabilities can be addressed subsequently. Note that the solutions implemented for the highest priority vulnerabilities may generate, modify, or reorder lesser vulnerabilities, so reassessment is needed to find the new highest priority vulnerability in the new system. Ideally, any interventions made will build on existing food safety and food quality systems instead of jettisoning them. Be aware, however, that improved or bolstered policies and strategies that principally serve food quality goals may not also serve food defense goals. "HACCP and other food safety systems designed to control naturally occurring microbial pathogens cannot anticipate and protect against individuals committed to using the food system as a means of public health or economic terrorism without significant modification" (Kennedy and Busta, 2013, p. 103).

An inhibition to the motivation an organization needs to create a food defense plan is that justifying the return on investment is difficult until it can be seen retrospectively. Basically, food defense preparation is brand protection. Unfortunately, once the food defense incident has occurred, it is too late to create plans for efficient mitigation, response, and recovery: "the effectiveness of a response depends to a great extent on the... preparedness plans that are developed and implemented long before any event occurs" (World Health Organization, 2008, p. 23).

According to PPD-8, a food defense emergency preparedness plan should include five frameworks: prevention, protection, mitigation, response, and recovery (Obama, 2011). Below are some of the strategies that organizations could implement for each of these frameworks. In the current status of food defense, the prevention, protection, and mitigation goals lie mostly in the hands of the food industry. Incident detection, rapid response, and public health services goals are currently the government's responsibilities. Collaboration on all emergency preparedness frameworks between the food

industry and the government agencies is promoted to advance the overall security of the food system. "The purpose of preparedness planning is to build a response system that links all the players needed for effective management of an emergency and to develop coordination, communication and integration among local, regional and national resources" (World Health Organization, 2008, p. 26).

Prevent

The goal of the prevention framework is to avoid or minimize the possibility of an intentional contamination event from happening. "Prevention, although it can never completely be effective, is the first line of defense" (World Health Organization, 2008, p. 1). The intelligent adversary theory says that no matter how many preventive measures there are in place, the complexity of the food system is such that there will always be another vulnerability, and the adversary will find it. Prevention is achieved by industry action with government direction. One key step the food industry can take is training employees in food defense. The NCFPD has created a curriculum framework for trainers to create food defense training materials (Fredrickson *et al.*, 2012).

Perhaps one of the most valuable ways to ensure food protection is to first focus on the people involved. The WHO recommends employers to screen employee backgrounds for security concerns, and all staff should be trained to identify and address suspicious behavior or unexpected visitors (World Health Organization, 2008). Creating a food defense culture among the food industry's employees is a way to utilize human resources to achieve food defense goals. Trained personnel may be more effective at stopping a perimeter breach or other suspicious activity than sampling methods, access restriction methods, or locked doors. The FDA's ALERT model can be used to train employees in food defense, and FDA's 'See Something, Say Something TM' campaign is one tool to establish a food defense culture. The human resources department of a company can assist greatly in screening employee applications to exclude aggressors attempting to gain access to the production line and to address any reasons that may motivate a current employee to undermine the security measures in place. Similar to that of a food quality program, food handlers should roll food defense goals into their supplier quality control program. Chemical cleaners and other industrial chemicals should be stored behind a locked door, and use of these chemicals should be documented so that anomalies and missing chemicals can be investigated.

Protect

Protecting the food system means halting an intentional contamination event that is currently underway. This involves restricting access to the foodstuffs themselves. At the processing plant, sensitive production floors (i.e., finished product with no further control step, open vats, or conveyers that give direct access to the production line) should have controlled access so that only authorized personnel may access them. Any visitor should be documented and easily identified so that personnel on the production floor can easily identify unauthorized people in the plant. Have a visitor agreement policy that each visitor must agree to the company's food defense goals. Outside of the production plant, surveillance cameras, physical barriers, and guards can deter any adversaries from entering the plant.

At the food product level, tamper-evident or -resistant packaging should be used and consumers should be informed not to consume any food that has been tampered with. It is critical to maintain the integrity of the food product after processing because if contamination occurs after the final control step, there may be no subsequent treatments to eliminate the contaminant before the consumer eats the food. Firms should ensure that contamination after this point in the supply chain is extremely unlikely and could be reliably detected before sending the product to consumers.

Mitigate

The goal of mitigation is to reduce morbidity, mortality, and economic loss after an incident occurs. A robust recall plan could remove contaminated products from distribution centers and shelves before it reaches consumers. A strong recall plan is founded in reliable tracing mechanisms for where the inputs for a product come from and where the product goes after processing. Rapid communication with a network of emergency response agencies and all nodes of the supply chain will be very important for the success of a recall. According to the Institute of Food Technologists, creating a product tracing plan relies on identifying critical tracking events (e.g., transfers of products to other handlers and processing steps) and recording and communicating key data elements (e.g., unique item identification codes) at each critical tracking event (Institute of Food Technologists, 2011). Creating a consistent system of monitoring tracking events and key data elements will drastically improve the food system's ability to minimize morbidity and mortality after a food defense incident.

Respond

The response to a food defense emergency is intended to save lives after an incident has occurred and contaminated product has already been consumed. Emergency response is when the critical tracking events and key data elements established in the mitigation planning are put to use. A response plan includes protocols to notify appropriate groups of the incident (including government, food industry, and the public), and how each potential scenario, including attacks on other facility utilities, will be handled (Biegel and Beach, 2010). It is essential that a response plan be in place before an attack happens so that the ensuing response is efficient and effective. Outlining the collaboration plan with local, tribal, state, and national emergency response agencies beforehand will ensure that the response itself will run as smoothly as possible. Depending on the magnitude of the threat, the capacity of municipal healthcare systems may be tested to respond to a large number of illnesses in a short period of time.

Decontamination and disposal of the contaminated food is necessary after it has been identified. The appropriate decontamination method is dependent on the threat agent used and the characteristics of the food matrix. In some cases, thermal processing can inactivate toxins and chemical sanitizers may be appropriate for other cases. The presence of the threat agent and these interventions, certainly, render the food inedible, and it must be disposed of safely after decontamination.

Recover

The challenge of food system recovery is regaining market access, public trust, and business continuity. Economic loss due to tarnished confidence in the safety of a particular food product is one of the lasting impacts of an intentional contamination incident. In 2008 and 2009, Peanut Corporation of America's (PCA) *Salmonella* outbreak resulted in the largest recall in US history and eventually forced PCA out of business. The total industry loss is an estimated US$1 billion (€778 million) (Kennedy and Busta, 2013). If a malicious contamination event could impact as many products as the PCA *Salmonella* outbreak, the economic impact could be devastating. The Chilean grape controversy discussed above in the Section Highlighted Food Defense Incidents demonstrates that economic losses extend to the global stage if countries impose trade limitations due to an incident in another country, and "intentional contamination of a particular food becomes more attractive as a target as the magnitude of various economic consequences increases" (Kennedy and Busta, 2013, p. 97).

Detailed food defense plans that include multiple layers of security help to prevent and protect against a food defense incident. Rapid recall systems and swift emergency management are needed to mitigate the hazard and respond efficiently. Business continuity plans and best practice public risk and crisis communication (discussed further in the Section Risk and Crisis Communication) are the key to maintaining a business market and public trust. See the list of relevant web pages for the US Department of Agriculture and FDA guidance documents for stakeholders in the food system on their respective 'Food Defense and Emergency Response Guidance' websites.

Risk and Crisis Communication

In addition to the direct impacts malicious contamination of the food system may cause, a food defense incident will have social and political impacts as well. Such an event may cause the public to lose confidence in the government's ability to keep its citizens safe and in the food industry's ability to make safe food. The purpose of good public risk communication before, during, and after a food defense incident is to mitigate public panic, dispel false information, and minimize the impact on public trust of the government and food industry.

Mass communication can serve as a double-edged sword during risk and crisis communication. The ability to deliver accurate information quickly is an advantage over misinformation, but the torrent of perceptions of risk can spread unnecessary panic just as quickly. Public media contributes to the 'available heuristic' – everyone remembers the extremes of the experiences while putting little importance on the much more common normal conditions of the day-to-day life. Cass Sunstein says that this phenomenon "can lead to a grossly overestimated sense of risk" (Sunstein, 2004 cited in Dalziel, 2009, p. 4) because one's panicked perception of the risk is much greater than its statistical reality. Some channels of public communication may intensify or exaggerate the status of a risk or a crisis, causing unnecessary outrage and anxiety.

There are risk and crisis communication best practices for government and industry in the literature. When an organization creates food defense policies, it is best to also determine communication methods at the same time. Note that food defense policies and communications are best when proactively determined before the incident occurs, not reactively after a crisis. Communication methods should be designed to align well with other policies, and designing both of them concurrently is an effective way to achieve that. Viewing risk and crisis communication as a constantly adapting process gives organizations the freedom to react accordingly to contextual dynamics of the particular scenario. New information about a given risk or crisis is constantly coming in, and often in unpredictable ways, so communication policies that allow for dynamic adaptation will serve best. Overall, risk communicators can trust that the public will receive honest, approachable, and transparent communication most positively. Risk communicators should also collaborate with credible and trusted sources to ensure that the information shared is accurate (Sellnow *et al.*, 2009).

Drafting risk and crisis communication messages requires a keen understanding of the particular audience that will receive the message. "Perceptions of risk are socially and culturally constructed" (Sellnow *et al.*, 2009, p. 23), so messages should be crafted with demographics such as age, gender, education, and culture considered. Risk communicators should also know that the public may have diverse interpretations of the risk, not just one. The diversity in perception should be acknowledged instead of ignored because the social implications of accusing the public of adopting a single perception will complicate risk communication in the future. Risk communication will be most effective if there is a relationship between the communicating parties. Relationships between parties should be built by including the public in risk assessment and communication questions (aka 'risk sharing') so that the public has a role in understanding the risk at hand.

Ethics are intimately involved in communicating with the public about potential health hazards. The NCFPD recommends listening to the public's needs and communicating with compassion, concern, and empathy during crises (NCFPD, n.d.). In addition, goals related to the ethical treatment of people should be paramount over economic concerns: "goals such as consumer safety must be prioritized over secondary goals of monetary gain or reputational maintenance" (Anthony and Sellnow, 2011, p. 441).

Because of the globalized food system, food defense is a global issue. To maintain the safety and trustworthiness of the global food supply, the food industry, all levels of government, and academia must collaborate to create robust preparedness systems for food defense.

Food Security, Market Processes, and the Role of Government Policy

CP Timmer, Harvard University, Cambridge, MA, USA, and Australian National University, Canberra, Australia

© 2014 Elsevier Inc. All rights reserved.

Introduction

Modern analyses of food security list five essential components: availability of food on farms and in markets, access to that food by all households, effective utilization of the food within the household (a function of food safety, nutritional status, and health), the sustainability of the food system that delivers these components, and its stability (Timmer, 2012). This definition stresses the elements that individuals and households require to be food secure, but food security is also an important objective at the national level, where political leaders can be held responsible for failures and successes in maintaining accessible supplies of staple foods at stable prices, especially in major urban markets where many consumers procure their food. (This will be chapter 33 in the *Encyclopedia of Agricultural Sciences* to be published by Elsevier. It draws on much of my research and writing over the past several decades, and especially on Timmer (2000 and 2013). David Dawe and Casey Friedman provided very helpful comments, but are not responsible for the arguments here).

At the global level, considerable attention is focused on both short- and long-run balances between food production and food consumption. Rising food prices suggest that the production race is being lost to rapid gains in food consumption – a 'Malthusian' world where population growth and higher incomes cause food demand to outstrip the resource base for food production. Falling food prices, however, suggest that expanded agricultural land, better water control, and improved technologies are generating food surpluses. In this 'Sen-ian' world, access becomes the limiting factor for household food security, not availability (Sen, 1981).

In both worlds, food prices are a key signal about what is happening to food security. Two dimensions of food prices are important: their average level and their volatility. Price spikes and collapses can create risks and poverty for consumers and farmers even when average prices are affordable to the poor and create adequate incentives for farmers. Although highly unstable food prices have negative consequences at the micro level for household-level decision makers, food price instability also has a deeper and more insidious impact: it slows down economic growth and the structural transformation that is the pathway out of rural poverty (Timmer, 1989, 2009a). Thus, food price instability really hurts the poor in both the short run and the long run.

To see this, consider a very simple model of food security that focuses on the short run versus the long run, and on the macro level (of policymakers) versus the micro level (of household decision makers) (see **Figure 1**). When the global economy is reasonably stable, and when food prices are well behaved, policymakers at the national level can concentrate their political and financial capital on the process of long-run, inclusive growth. Keeping the poor from falling into irreversible poverty traps is easier and less costly in a world of stable food prices, and the poor are able to use their own resources and entrepreneurial abilities to connect (via the small horizontal arrow) to long-run, sustainable food security for themselves.

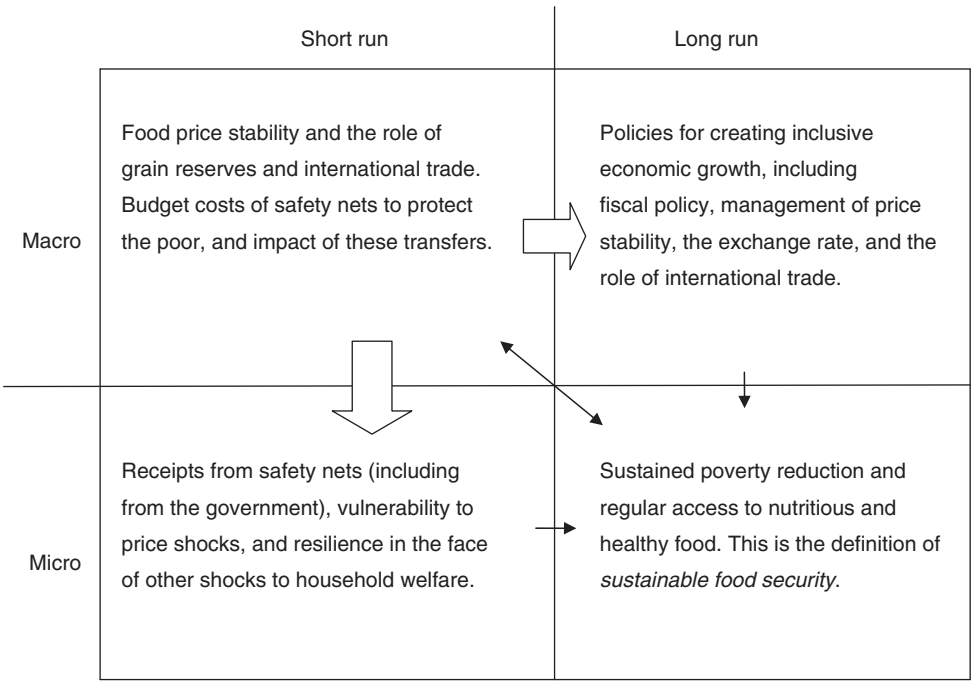

Figure 1 Basic framework for understanding food security issues.

 doi:10.1016/B978-0-444-52512-3.00033-4

If the food economy is highly unstable, constantly in crisis, policymakers spend all of their time and budget resources in the 'upper left' box, trying to stabilize food prices and provide safety nets for the poor. During food crises, vulnerable households often deplete their human and financial capital just to stay alive. This is the world of poverty traps and enduring food insecurity. One is also trapped in short-run crisis management, both macro and humanitarian. Donors such as United States Agency for International Development can be trapped in crisis mode as well as governments, and end up spending their human and financial resources on emergency relief rather than longer-run development strategies and investments.

With success in achieving the objectives in the upper right and lower left boxes, market forces gradually – over decades – bring the poor above a threshold of vulnerability and into sustained food security (connecting macro to micro and short run to long run). The goal is to get to the 'lower right' box where households have sustainable access to food in the long run. That is, they are food secure.

This result is achieved by using a 'food policy perspective' (Timmer, Falcon and Pearson, 1983). This perspective stresses the need for analytical and policy flexibility to cope with market instability. Such flexibility is not a natural feature of domestic policymaking, in the food sector or elsewhere, and providing the analytical tools for understanding how to create flexible responses to both high and low price environments is a real challenge. The starting point is usually to understand the food marketing system, which transforms commodities in a farmer's field in time, place, and form, into food on the table. It is impossible to understand the challenges facing efforts to eliminate hunger without understanding the role of markets and how the food marketing system operates. This is the food policy perspective.

The food policy agenda includes rapid and sustained poverty reduction. There are four basic food policy objectives, and all four are important:

1. Faster economic growth (the 'efficiency' objective),
2. More equal distribution of income from that growth (the 'welfare' objective'),
3. A guaranteed nutritional floor for the poor (the 'safety net' objective), and
4. Secure availability and stable prices in food markets (the 'food security' objective).

There are many trade-offs (and overlap) among these objectives, and substantial analysis of a country's food system is necessary to understand, if even roughly, the magnitudes of the trade-offs. The central organizing theme of the analysis is the 'food price dilemma,' an explicit recognition that a single market-clearing food price cannot satisfy all four objectives simultaneously – a 'pure' market solution does not work. Additional policy instruments are needed, but they all need to operate compatibly with market prices. The most important lesson is the centrality of food prices – and the signals they send to farmers, traders, consumers, and finance ministers. The behavior of these decision-making agents dictates market outcomes, but also responds to those market outcomes. The 'macro' food system that food policy analysts need to understand encompasses micro behavior on the farm and in the household, market-level behavior by traders, processors and retailers, and macroeconomic responses by policymakers.

In a market economy (the only kind of economy with a successful track record of raising labor productivity, and hence living standards, over many generations), markets play three key roles: First, as stressed by technical planners, they play an engineering role by moving inputs to farmers and food to consumers. Even socialist, planned economies have to use markets in this role.

However, there are two deeper roles for markets that provide market economies their distinguishing strengths (and often harsh outcomes). First is the role of markets in price discovery – what is a commodity (or service) 'worth' in monetary terms? These terms dictate the rate of exchange and determine such important values as the price of rice or of wages for unskilled labor. Price discovery is about scarcity, the distribution of incomes, and who gets what.

However finally, markets serve as the arena for allocating society's scarce resources to meet the virtually unlimited needs and desires of consumers. This allocation process, when joined to reasonably efficient price formation, is the reason market economies have outperformed other forms of economic organization over the long haul. Efficiency in resource allocations is simply critical to raising economic output in a sustainable fashion, and thus to reducing poverty and hunger.

Simply 'getting prices right' in markets will not solve the problem of hunger. However, it is also not possible to 'plan' one's way out of hunger by making markets do one's will. The trick, and only a few countries (mostly in East and Southeast Asia) have managed it smoothly, is for government policy and markets to work together to bring poor households into a growing economy that is based on a productive, sustainable, and stable food system. Only then can one end hunger, and keep it ended.

From this policy perspective, food security as a global issue presents an enormous paradox. At one level, steady progress has been made in the past half century in bringing much of the population out of poverty and hunger. Measured by the key determinants of food security – improved availability, access, utilization, and stability – food security has been improving. Large pockets of food insecure populations remain, especially in Sub-Saharan Africa and South Asia, but because of rapid economic growth, aggressive food price stabilization efforts, and/or safety net programs that deliver food to the poor, the rest of Asia and Latin America are coping reasonably well with their food security challenges.

At the same time, food security strategies and policies are in almost total disarray. A fundamental disconnect exists between what most countries say their food security strategies are, and what policies they are actually pursuing. The disconnect is most manifest with rice policy in Asia, where high prices for rice farmers are implemented to 'reduce poverty,' when in fact most of the poor and hungry in the region are net rice buyers, and thus suffer more hunger and poverty from high rice prices. However, many countries do not have coherent strategies to improve their food security. An important reason for this disconnect is a basic misunderstanding in the political arena of

the interconnected role of markets and government policies in providing sustainable food security.

An Overview of Food Security Dynamics

The Food and Agriculture Organization's (FAO's) flagship publication, The State of Food Insecurity in the World 2012, provides a sophisticated new methodology for estimating the prevalence of undernutrition and uses it with the latest data to present the best indicators available on the state and dynamics of food security at the country level between 1990–92 and 2010–12 (FAO, WFP and IFAD, 2012). **Table 1** summarizes the key data for the world, Latin America, Sub-Saharan Africa, and the subregions of Asia, for comparative purposes. For each region, data are shown for 1990–92, 2000–02 and 2010–12, with changes calculated between decades.

Four food security indicators are shown for each region. First is the 'prevalence of undernutrition,' the 'headline' indicator used to measure progress on the Millennium Development Goals (goal 1, target 1.9). It is the proportion of the population at risk of caloric inadequacy and is the traditional FAO measure of hunger. Second is a new measure of average dietary energy supply adequacy. This indicator expresses each country's or region's average supply of food calories available for consumption (including imports) as a percentage of average dietary energy requirements for the population, as calculated by FAO. Third is a measure of the depth of the food deficit facing the undernourished, also as calculated by FAO. It indicates how many calories would be needed to lift the undernourished from their status, normalized by total population, everything else held constant. The measure shown in **Table 1** uses the 'depth of the food deficit in kilocalories per capita per day' as a percentage of the minimum dietary energy requirement (MDER), so that it is on a similar scale as the food supply measure.

Finally, a 'food security gap' is calculated for this article to indicate the rough balance between food supplies available and the depth and extent of hunger. This gap is simply the

Table 1 Food Security Indicators

Region/Indicator	*Time period (and change from previous time period)*				
	1990–92	*2000–02 (change)*		*2010–12 (change)*	
World					
Prevalence[a]	18.6	14.9	(−3.7)	12.5	(−2.4)
Food supply[b]	114	117	(+3)	121	(+4)

Food security gap	−12.3	−0.4	(+11.9)	15.7	(+16.1)
Developing East Asia					
Prevalence	20.8	14.3	(−6.5)	11.5	(−2.8)
Food supply	107	117	(+10)	124	(+7)
Food deficit	8.2	5.2	(−3.0)	4.0	(−1.2)
Food security gap	−1.2	11.8	(+13.0)	20.0	(+8.2)

[a]Prevalence of undernourishment.

[b]Average dietary energy supply adequacy.

[c]Food deficit is the 'depth of the food deficit in kilocalorie per capita per day' as a percentage of minimum dietary energy requirement (MDER).

[d]Food security gap = (Supply − 100) − Food deficit = FSgap. When FSgap = 0, there is exactly enough 'surplus' food supply to offset the entire food energy deficit.

Source: Reproduced from FAO, WFP, IFAD, 2012. Economic growth is necessary but not sufficient to accelerate reduction of hunger and malnutrition. The State of Food Insecurity in the World 2012. Rome: FAO.

'surplus' food supply available (food supply – 100) minus the food deficit, as calculated and reported in Table 1. A negative gap means the food deficit is larger than the food surplus, with the inevitable consequence that people will be hungry even with equitable distribution. Sharply positive levels of the gap mean there is plenty of food for all. (Note that the 'supply' variable makes no allowance for the state of nutrition of the population. The 'population normalized' food deficit measure indicates how much food energy would be needed per capita to bring the undernourished population up to the minimum energy requirement. Both indicators need to be examined together to gain an understanding of the relative importance of food availability and food access in driving the extent of undernutrition. The 'food security gap' measure does this in a simple (if crude) way. Substantial hunger (high 'prevalence') in these environments suggests a highly unequal distribution of economic resources. This measure of the food security gap is a particularly sensitive indicator of progress (or lack thereof) in reducing undernourishment, and whether availability or access is the limiting factor.

It is clear from the data in Table 1 that substantial progress in reducing food insecurity has been made over the past two decades. Prevalence of undernutrition at the global level has fallen from 18.6% in 1990–92 to 12.5% in 2010–12, a decline of 6.1% points (almost a third).

Both Southeast Asia and Developing East Asia have made enormous progress in lowering food insecurity in the past two decades, with prevalence dropping by 18.7% points and 9.3 points, respectively. Most remarkably, both regions moved from negative food security gaps to sharply positive ones. In Southeast Asia, a very large negative gap of −12.3% was transformed into a very large positive gap of 15.7 points in just 20 years. Improved supplies (up 20%) and sharply lowered food deficits (down 8%) contributed to this amazing performance.

Significant challenges remain, of course. The prevalence of undernutrition in Sub-Saharan Africa remains very high, 26.8%, although the trend is for modest improvements. In South Asia the rate has fallen by 9% points, although it remains relatively high at 17.6% undernourished in 2010–12.

As noted, the most sensitive indicator of changes in food security status is the 'gap' measure. Only Sub-Saharan Africa and South Asia continue to have negative gaps, indicating an overall shortage of food available in the countries in each region, and even these negative gaps have narrowed significantly. At one level, the relationship between an improving food security gap and reductions in prevalence of malnutrition is obvious. More food and smaller deficits translate into less hunger. However, there are nuances to the relationship. In particular, the relationship is not linear – there are clear diminishing returns to improving the food security gap in terms of lowering the prevalence of undernutrition. (The statistical relationships used to calculate the rate of diminishing returns are based on annual data for individual countries in each of the regions.) Food insecurity becomes less a problem of food availability and general poverty, and more a structural problem of people 'left behind.' Structural poverty and hunger require a much more sophisticated and targeted approach than the 'propoor growth with stability' approach that has worked so well in the past, especially in Asia (Timmer, 2004).

The Three Fundamental Transformations Needed to Ensure Food Security

Three basic transformations drive the link between economic development and food security (Timmer, 2009a): Structural, agricultural, and dietary. Especially in Asia and Latin America, accompanying these three basic transformations have been rapid changes in the entire food marketing system (led by the 'supermarket revolution,' see Reardon and Timmer, 2012), and in the growing importance of urban consumers as drivers of a country's food system. The 'endpoint' of the structural transformation – the full integration of factor markets between rural and urban areas – is now within sight in the richest transition countries, but remains a challenge to poor- and middle-income countries.

Structural Transformation

The structural transformation involves declining shares of agriculture in gross domestic product (GDP) and employment, almost always accompanied by serious problems closing the gap in labor productivity between agriculture and nonagriculture. The basic cause and effect of the structural transformation is the rising productivity of agricultural labor. Figure 2 presents an especially graphic illustration of the structural transformation in 86 countries between 1961 and 2000. Each red square represents the share of agriculture in total employment for a particular country and year. Similarly, each blue circle represents the share of agriculture in economic output, or GDP, for the same country and year. Finally, each green cross is the difference between these two shares measured so that the value, which is simply the gap in labor productivity between agriculture and nonagriculture, is negative

The historical path of structural transformation has been accompanied by falling food prices, leading to a 'world without agriculture' (Timmer, 2009a). However continued financial instability, coupled with the impact of climate change, could lead to a new and uncertain path of rising real costs for food. Such a path would lead to a reversal of structural transformation (Timmer and Akkus, 2008). Management of food policy, and the outlook for sustained poverty reduction, will be radically different depending on which of these alternatives materialize.

The structural transformation involves four main features:

1. A falling share of agriculture in economic output and employment,
2. A rising share of urban economic activity in industry and modern services,
3. Migration of rural workers to urban settings, and
4. A demographic transition in birth and death rates that always leads to a spurt in population growth before a new equilibrium is reached.

These four dimensions of the historical pathway of structural transformation are experienced by all successful developing economies; diversity appears in the various approaches governments have tried to cope with the political pressures generated along that pathway. Finding efficient policy mechanisms that will keep the poor from falling off the

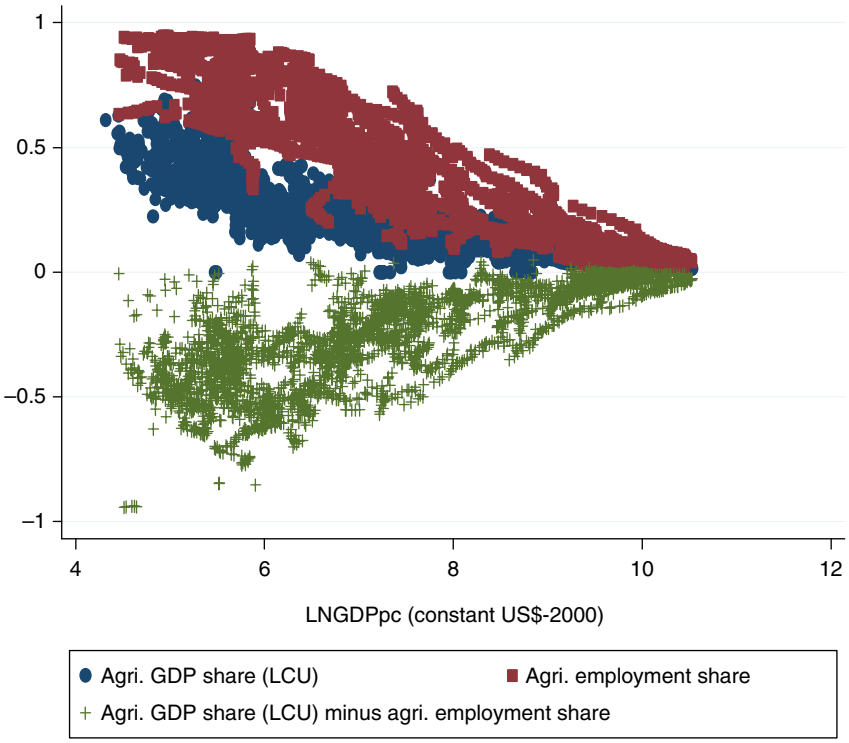

Figure 2 The structural transformation in 86 countries from 1965 to 2000. Reproduced from Timmer, C.P., Akkus, S., 2008. The structural transformation as a pathway out of poverty: Analytics, empirics and politics. Working Paper 150. Washington, DC: Center for Global Development.

pathway altogether has occupied the development profession for decades. There are three key lessons.

First, the structural transformation has been the main pathway out of poverty for all societies, and it depends on rising productivity in both the agricultural and nonagricultural sectors (and the two are connected). The stress on productivity growth in both sectors is important, as agricultural labor can be pushed off the farms into even lower productivity informal service sector jobs, a perverse form of structural transformation that has generated large pockets of urban poverty, especially in Sub-Saharan Africa and India. (Both of these cases have been documented in the Stanford Symposium Series on Global Food Policy and Food Security in the twenty-first century (Badiane, 2011; Binswanger-Mkhize, 2012).) It is no accident that these are the two regions of the world where food insecurity remains severe.

Second, in the early stages, the process of structural transformation widens the gap between labor productivity in the agricultural and nonagricultural sector – a process shown in Figure 2. This widening puts enormous pressure on rural societies to adjust and modernize. These pressures are then translated into visible and significant policy responses that alter agricultural prices. The agricultural surpluses generated in rich countries because of artificially high prices then cause artificially low prices in world markets and a consequent undervaluation of agriculture in poor countries. This undervaluation over the past several decades, and its attendant reduction in agricultural investments, is a significant factor explaining the world food crisis in 2007–08 and continuing high food prices.

Third, despite the decline in relative importance of the agricultural sector, leading to the 'world without agriculture' in rich societies, the process of economic growth and structural transformation requires major investments in the agricultural sector itself. This seeming paradox has complicated (and obfuscated) planning in developing countries as well as donor agencies seeking to speed economic growth and connect the poor to it. Owing to active policy concerns about providing food security to their citizens, countries in East and Southeast Asia largely escaped much of this paradox, but Sub-Saharan Africa has not.

For poverty-reducing initiatives to be sustainable over long periods of time, the indispensable necessity is a growing economy that successfully integrates factor markets in the rural with urban sectors, and stimulates higher productivity in both. That is, the long-run success of poverty reduction, and with it, improvements in food security hinge directly on a successful structural transformation. The historical record is very clear on this path.

Managing the ingredients of rapid transformation and coping with its distributional consequences have turned out to be a major challenge for policymakers. 'Getting agriculture moving' in poor countries is a complicated, long-run process that requires close, but changing, relationships between the public and private sectors. Donor agencies are not good at this. More problematic, the process of agricultural development requires good economic governance in the countries themselves if it is to work rapidly and efficiently. Aid donors cannot hope to contribute good governance themselves – and may well impede it.

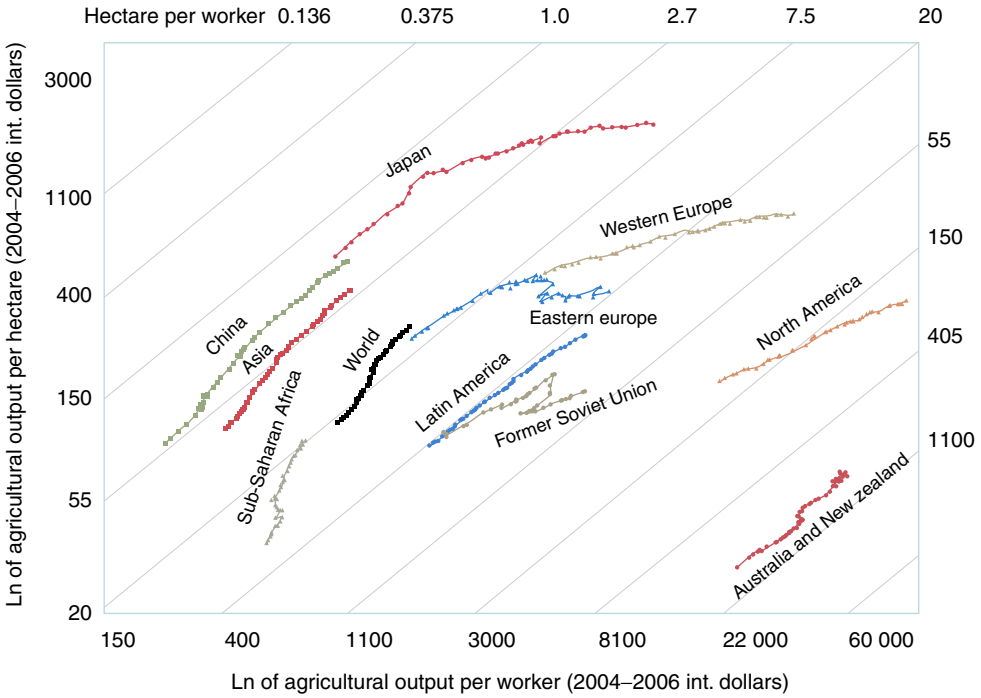

Figure 3 Land and labor productivity in agriculture, 1961–2010. Reproduced from Philip, P., 2011. African agricultural productivity growth and R&D in a global setting. Stanford Symposium Series on Global Food Policy and Food Security in the 21st Century, October 6, Stanford University.

The strong historical tendency toward a widening of income differences between rural and urban economies during the initial stages of the structural transformation is now extending much further into the development process. Consequently, with little prospect of reaching quickly the turning point, where farm and nonfarm productivity and incomes begin to converge, many poor countries are turning to agricultural protection and farm subsidies sooner rather than later in their development process. The tendency of these actions to hurt the poor is then compounded, because there are so many more rural poor in these early stages.

Agricultural Transformation

Although the structural transformation is a general equilibrium process that is not easily visible from inside the agricultural sector, the changing demand and productivity patterns induce significant change within the sector itself (Timmer, 1988). This agricultural transformation is driven by changing domestic demand, opportunities for international trade, commercialization of decision making, and technical change that is both commodity specific; for example, 'green revolution' varieties of wheat and rice; and sector-wide-better inputs, improved knowledge, communications, infrastructure, and financial intermediation. Nonstaple commodities, such as palm oil, and nonfood commodities such as coffee and rubber, play larger roles in certain circumstances. The potential for commodities to be grown as raw materials for biofuel production – especially maize, palm oil and cassava – might be a future driver of the agricultural transformation (with highly uncertain consequences for food security).

No single measure of the pace and extent of agricultural transformation captures the complexity and heterogeneity of the process – much is country and time specific. The most graphic and general representation of the process of agricultural transformation is the 'Ruttan-a-gram,' which measures productivity per hectare on the vertical axis and productivity per worker on the horizontal axis (see Figure 3). This two-dimensional perspective on agricultural development was developed by Hayami and Ruttan (1985), where it was used as a powerful tool to demonstrate the multiple paths to successful agricultural transformation. The 'Asian Path' relied heavily on new biological and chemical technologies to raise yields in land-scarce, labor-surplus environments, whereas mechanical technologies were used to raise labor productivity in land-abundant, labor-scarce environments. Japan characterized the former approach for raising agricultural productivity; the United States, Canada, and Australia/New Zealand characterized the latter. Western Europe was, appropriately, in between these two more extreme approaches.

Figure 3 shows the pathways of productivity change in the agricultural sectors of major regions, as well as the world total. Two things are striking. The first is the rapid pace of gain in most regions (indicated by the overall length of the line for each country or region because both axes are measured in logarithms). Japan and China have both seen major gains in labor and land productivity over the past half century, although average farm size has only started to increase in Japan in the past several decades; most of Europe has seen gains in labor productivity via larger farm size, although Eastern Europe and the Former Soviet Union suffered severe reversals after the fall of communism. The most striking feature of Figure 3, however, is the stagnation of growth of labor

productivity in Sub-Saharan Africa. Although yields per hectare are increasing slowly, there has been virtually no gain in labor productivity in agriculture in half a century.

The second striking feature is that land consolidation has barely begun at a global level. Indeed, farm size continues to get smaller on average, driven by the gradually shrinking farms in Asia and the more quickly falling farm size in Africa. Farm size has been virtually constant in Latin America. Uncertain land ownership and tenancy laws in Asia and Sub-Saharan Africa may account for some of this 'stickiness' in reported farm size. Outmoded statistical definitions may also be a factor: workers may be counted in the agricultural labor force even if most of their income is derived from off-farm sources.

Dietary Transformation

The basic drivers of changed dietary patterns are Engel's Law (the share of food in budget expenditures falls with higher incomes, thus providing a buffer against the welfare impact of sudden changes in food prices) and Bennett's Law (the share of starchy staples in the diet falls with higher incomes, as a deep, perhaps 'hard-wired,' desire for diversity in the diet can be expressed), but long-run changes in relative prices, changing demographics, as well as exposure to 'foreign' eating patterns also seem to have an impact.

As with the agricultural transformation, no single measure captures the complexity of dietary changes, and much is specific to local customs and tastes. As one example of the complex changes that are underway in a rapidly developing part of the world, Figure 4 presents several important dimensions of the dietary transformation that is underway in Southeast Asia, with the area of each pie chart proportional to average energy intake per capita for each of the 6 years depicted. Four things are striking. First, total caloric intake has risen steadily over the past half century, by 0.8% per year. In 1961, average food availability per capita, as measured by FAO Food Balance Sheet data, was just 1814 cal per day. Most citizens of Southeast Asia would have been chronically hungry then. By 2009, the most recent year for which data are available, food available per capita per day reached 2657 cal. At that level, hunger will not be common and obesity will be a rising problem.

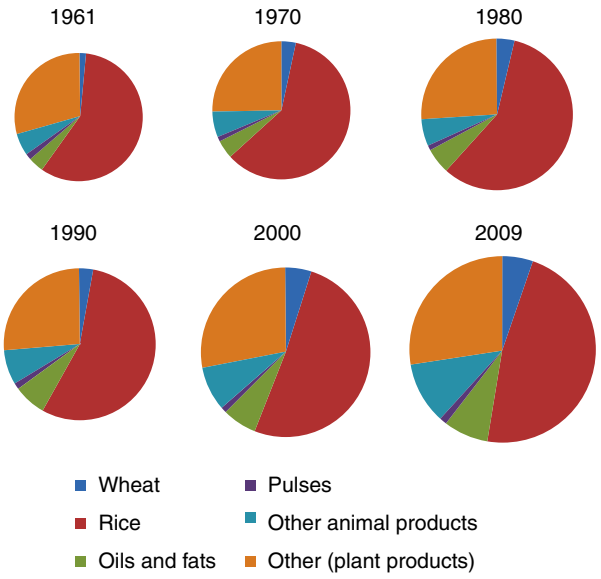

Figure 4 The dietary transformation in Southeast Asia. FAOSTAT, 'Food Balance Sheets,' FAO of the United Nations.

Second, the starchy staple ratio – the share of calories coming from cereals and starchy roots – fell from 74.8% to 62.1%. Intake of animal protein nearly tripled. The quality of the diet in nutritional terms has improved markedly, although the doubling of fat in the diet is a worrisome sign.

Third, rising consumption of animal products will require a modern feed industry to supply domestic producers of poultry, livestock, and aquaculture products, unless imports of final goods increase drastically. Domestic farmers have a rapidly growing market for feedstuffs, but at the moment a very large proportion of Southeast Asia's feed ingredients, especially maize and soy meal, is imported.

Finally, wheat calories are increasing 8% per year and wheat consumption is more than a 10th of rice consumption. Southeast Asia imports all of its wheat – Indonesia will surpass Egypt in 2013 as the world's largest importer of wheat. A volatile world market for wheat will increasingly be seen as a threat to food security in Southeast Asia, but national agricultural development strategies cannot be used to cope with that threat. With rice becoming less important to food security in the region, and wheat and feed grains becoming more important, management of food security will increasingly be a trade and macroeconomic issue rather than an agricultural issue.

The Changing Food Marketing System

The food marketing system is changing rapidly, especially as modern supply chains evolve to provision supermarkets (see Figure 5), and as concerns for food safety and origin are reflected in the purchasing decisions of increasingly affluent consumers. Modern supply chains and supermarkets change the nature of farm–market–consumer interactions. The spread of modern supply chains has the potential to be a real problem for food security.

Increasingly, modern supply chains are transmitting demand signals from consumers who are shopping in supermarkets, back up the food system, level by level, to processors, farmers, and input suppliers. Traditionally, each cell in the food system depicted in Figure 5 was connected locally by small traders operating with minimal capital and primitive technology (Reardon and Timmer, 2007, 2012). Modern supply chains are far more integrated into the farm-level procurement systems of supermarkets and are coordinated by these firms as they seek to 'drive costs out of the system.'

Four important trends emerge from the '10-wheeler' perspective in Figure 5, when it is overlaid with changing food consumption patterns in a given country or region. First, the vertical boxes are increasingly connected by market and nonmarket forces. One key conclusion for suppliers of technology in the private sector is that there can be no effective demand for inputs unless farmers are able to sell surpluses into the market. This market is increasingly controlled by procurement officers for supermarket chains, and their tendency to

	Food grain economy (starchy staples)	Non staple commodities (Fruits and vegetables, meat/ dairy, processed foods)
Farm inputs/ supplies	Smaller area possible higher yields, stress tolerance consumer quality	More value/hectare, but what role for small farmers (what 'assets' do they need to stay in ?)
Farm production (management and knowledge)	Very knowledge-intensive for good management practices; Access to inputs by farm size	Knowledge intensive; can there be effective extension for new technologies? Role of farm assets
Procurement/ logistics and wholesalers	Less rural consumption as workers leave; more transportation and storage; greater production instability with climate change	High transaction costs of dealing with small farmers; issues of quality control and product traceability
Processing and value added	Milling technology How to add value; branding?	Large share of consumer food expenditure is spent in this box
Retail/consumer welfare and health dimensions	Supermarkets as suppliers of food grains? Increased price stability through private actions? Problems of access by the poor?	Modern supply chains are funneling consumer demand back up the system. The food system is less supply driven.

Figure 5 Modernizing food supply chains: The '10-Wheeler' Model. Author design.

consolidate suppliers may counter the effort by governments seeking to include small farmers. However, successful efforts to reduce the transactions costs of incorporating small farmers into modern supply chains may simultaneously pay dividends by making these same farmers more accessible to modern input suppliers.

Second, there is a clear and rapid shift from the left side column of Figure 5 to the right side – from the 'starchy staple' sector to the 'diversified foods' sector. This shift reflects Bennett's Law (Bennett, 1954). This dietary diversification tends to improve the nutritional quality of the diet, although more processed foods and highly industrialized meat production raise nutritional, environmental, and food safety concerns.

Third, this increasingly diversified, market-driven food economy is more reflective of supply chain dynamics and consumer demand than in the past, which makes it more sensitive to rapid income growth and somewhat less sensitive to population growth. Especially where population growth is slowing quickly and income growth continues at a rapid pace, understanding the 'Engel elasticities' of the various items in the food shoppers' baskets (i.e., how demand for individual items responds to income growth), as well as other factors shaping consumer demand for food such as advertising, age structure, urbanization, and globalization of tastes, will be necessary for effective planning all the way back the chain to input supply.

Fourth, as consumers increasingly use supermarkets as the source of their purchased food staples, some surprising implications arise for food security. Traditionally, staples have been purchased in small retail shops with multiple grades and varieties available. Prices fluctuated according to local supply and demand conditions and often changed daily during periods of instability. The concentration of purchasing power into a handful of supermarket chains raises the possibility that procurement officers for food staples will encourage (force) their suppliers to maintain large enough stocks so that supplies will be reliable and that prices can be kept reasonably stable. Indeed, it is easy to imagine supermarkets, especially in East and Southeast Asia, where unstable rice prices are a threat to food security, beginning to compete for customers with a

promise of 'safe, reliable rice supplies, at a stable, fair price.' Rice price stability could become a private good rather than the public good it has been historically (Timmer, 1989, 2010). The whole debate over how to provide food security in settings where volatile food prices can threaten it will be transformed when most food is purchased in supermarkets. We are a long way from that situation in 2013, but supermarkets are increasingly important as a supplier of basic food staples in developing countries.

What Is Driving Food Security? The Changing Global Environment

The international context for domestic food policy decision making with respect to food security has changed substantially since the mid-twentieth century. Six basic trends stand out, especially with respect to expectations in the early 1980s:

1. Surprisingly rapid economic growth occurred, especially in Asia, with hundreds of millions of people pulled out of poverty. The strong connection between inclusive economic growth, especially in rural areas, and rapid reduction of poverty was simply not apparent in the empirical record in the early 1980s. The East Asian Miracle (World Bank, 1993) did not appear for another decade. This rapid growth validated the central theme of the food policy perspective, which is the unsustainability of poverty reduction efforts without higher economic productivity of unskilled, especially rural, labor. That theme remains powerfully relevant.
2. A communications revolution at both the household and international levels has radically reduced transactions costs and increased access to knowledge. Again, the centrality in the food policy perspective of markets and price formation to understanding food policy design and implementation was boosted because marketing margins narrowed under improved and more informed competition. Consumers and farmers both benefited from more competitive local food markets. The 'supermarket revolution' has merely accelerated these changes (Timmer, 2009b; Reardon and Timmer, 2012).
3. Global financial markets became interested in 'emerging economies.' The early 1980s were an era of fixed exchange rates, tight controls on the flow of foreign capital, and virtually no financial intermediation beyond state banks. At first, the influx of foreign capital in the 1990s was welcomed as a sign of confidence, but except for foreign direct investment in 'real' assets such as factories and real estate, the global financial interest in emerging economies was a two-edged sword. A rapid influx could cause currency appreciation and a loss of competitiveness; its rapid exit when the economy started to decline or foreign investors saw better opportunities elsewhere caused a crisis in local financial markets. Global financial integration came with very poorly understood risks, and 2009 demonstrated them clearly. The growth of foreign investments in land to produce food and/or biofuels for export – the so-called land-grabs – is controversial, but at least the capital cannot leave the country quickly. The injection of new capital into agriculture in poor countries may not be all bad. Much will depend on who benefits from the new production – foreigners or local farmers.
4. The rapid emergence in the 1990s of China and India as global growth engines meant a gradual shift in the drivers of demand for commodities and natural resources. Advanced economies had become more knowledge-driven and less dependent on energy, metals, and other basic commodities – including food commodities – to fuel their economic growth. The price depression for nearly all commodities in the 1980s and 1990s reinforced the view that the future depended on value added from skills and knowledge, not from exploitation of natural resources. However industrialization, especially as practiced by China and India, is a very intensive user of natural resources (and producer of greenhouse gases). By the turn of the millennium it was increasingly clear that the growth path of developing countries was the primary driver of commodity prices, starting with energy prices but quickly extending to food prices. The Malthusian challenge was back, but with two decades of neglected investments in raising agricultural productivity (because of the low agricultural prices), the challenge is turning out to be hard to meet.
5. High energy prices have turned out to be a 'game changer' for agriculture and the food economy. Once oil prices were high enough to justify using sugar, maize, cassava, or vegetable oils to produce gasoline or diesel substitutes, agricultural commodity prices became directly linked to oil prices. The concern to reduce emissions of greenhouse gases to mitigate climate change provided ample motivation to the US and European legislatures to mandate the use of domestic food crops to produce liquid fuels. The combination of legislative mandates, which provided essential risk coverage to investors in biofuel facilities, and high oil prices, which provided market-based incentives, led to a new set of linkages between agriculture and the energy sector. (The link between biofuel policies and food prices is complicated and depends on fundamentals in energy and food markets as well as on policies. This complexity has become the topic of intensive research, for examples, see de Gorter and Just (2010), de Gorter and Drabik (2012), and Naylor (2012).) There had long been a link on the supply side, as energy prices affected fertilizer costs, fuel costs for tractors and trucks, and the economics of global supply chains. The new link was through the demand side. Higher prices for energy translated directly into greater demand for food commodities to convert into liquid fuels. There is no way that agriculture can meet the nearly insatiable demand globally for liquid fuels, and having the food–fuel price linkage puts poor food consumers at serious risk.
6. Climate change is imposing itself as a reality on the increased probability of extreme weather events in general, and also on both global and localized food security outcomes in particular. The ecosystem services provided by the climate are a *sine qua non* for all agricultural production – photosynthesis remains the most efficient way to capture solar energy for human use. The most important effects of climate change on agriculture are likely to include a net global loss of agricultural land, changing crop suitability,

and an increase in the frequency of natural disasters. It will also have negative effects on other areas of agriculture broadly interpreted; climate change will reduce the carrying capacity of many rangelands and pose threats to fisheries and aquaculture production systems.

Climate change is expected to have highly variable effects on different regions; tropical and equatorial regions will bear the heaviest burdens, with Sub-Saharan Africa probably facing the greatest challenges, with some gains in yields and land availability in temperate regions. As rural poverty is concentrated in tropical and, in South and Southeast Asia, coastal areas, climate change is expected to have a disproportionate effect on the already vulnerable. The growing urbanization of poverty, the result of dysfunctional structural transformations (especially in Africa and India), may change the geographic incidence of the impact of climate change on the poor, but probably not the overall level (Ravallion, Chen and Sangraula, 2007; Badiane, 2011; Binswanger-Mkhize, 2012).

Agriculture also plays an important role in driving climate change, accounting for 14% of global greenhouse gas emissions, and this figure more than doubles when deforestation and other land-use changes are included. Forests, thus, are a crucial global natural resource for climate change mitigation. At the global level, the challenge of climate change for the international architecture in agriculture is to continue pushing toward an overarching global climate deal, while contributing to other schemes that support and provide incentives to the absorption and reduction of emissions at the country level. In-country 'climate-smart agriculture' adaptation projects and programs now form part of the food policy agenda. The challenge is to design, analyze, and implement these projects and programs.

The Way Forward

Several policy approaches to improving food security are under consideration. Which is best will depend on which global food price regime is likely to drive policy formation in the coming quarter century. The historical path of structural transformation with falling food prices, leading to a 'world without agriculture' is an obvious possibility (Timmer, 2009a). However, continued financial instability, coupled with the impact of climate change, could lead to a new and uncertain path of rising real costs for food with a reversal of structural transformation (Timmer and Akkus, 2008). Management of food policy, and the outlook for sustained poverty reduction, will be radically different depending on which of these global price regimes plays out.

Policy Approaches to Food Security in a Volatile Price Environment

There are three basic approaches to coping with the impact of high food prices once they hit world markets: domestic price stabilization; increasing supplies available in local markets; and providing safety nets to poor consumers. All three are directed at and must be managed by individual countries themselves, but donors and international agencies can play a substantial role as well in coordinating activities and providing resources, both financial and technical assistance.

The first approach is for individual countries to use market interventions to stabilize their domestic food prices. Such stabilization requires some capacity to isolate the domestic rice market from world markets and can only be implemented through government actions (although private traders can handle most of the actual logistics. Isolation from the world market does not, of course, guarantee more stable prices. Indeed, for most countries, open borders to world markets lead to greater price stability, as local shortages and surpluses can be accommodated through trade). Such isolation runs directly against the spirit and, for many countries, the letter of WTO agreements. However, it is a very widespread practice. Demeke, Pangrazio, and Maetz (2009) count 36 countries that used some form of border intervention to stabilize their domestic food prices during the 2007–08 crisis.

Such policies can have a large impact on the level of food insecurity, even at a global level. India, China, and Indonesia stabilized their domestic rice prices during the 2007–08 food crisis by using export bans (or at least very tight controls), thus protecting well over 2 billion consumers from sharply higher prices. The policies pursued by these three countries demonstrate the importance of understanding local politics in policy formation, especially food policy. Although the end results were similar – food prices remained stable throughout the crisis – the actual policies pursued in each country were quite different (Slayton, 2009; Dawe, 2010a). (The 'pass through' of price increases in world markets to the domestic economies of China, India, and Indonesia from early 2007 to early 2008 were 4%, 8%, and 3%, respectively. In each case, however, domestic rice prices were already higher than world prices, before the crisis hit (Dawe, 2010a).)

India, Indonesia, and China are big players in the global rice market, even if their actual trade is limited. As Dawe (2010b) emphasizes, there is a case to be made simply in terms of aggregate global welfare that stabilizing domestic rice prices in these large countries using border interventions might be both an effective and an efficient way to cope with food crises, even after considering the spillover effects on increased price volatility in the residual world market. Dawe points out that unstable supply and demand must be accommodated somewhere, and passing the adjustment to the world market may be both equitable and efficient in a second-best world where fast-acting and well-targeted safety nets are not available. One important advantage of successful price stabilization efforts in Asia is that they also stabilize price expectations among the many participants along the entire rice supply chain, and thus prevent the disastrous hoarding behavior that can generate extreme market shortages and severe price spikes (Timmer, 2010, 2012).

The second basic approach to coping with a food crisis is to stimulate additional supplies through fast-acting programs. Nearly all countries tried to do something along these lines during the 2007–08 crisis, whether by subsidizing fertilizer to get a quick production response or encouraging planting of short-season crops, even urban gardens. If the high prices

for food seen in the crisis actually get to farmers, they have strong incentives to search out these options themselves, but government assistance in gaining access to inputs or proper seed varieties can also help. In Asia, the short-run response of rice farmers to high prices was surprisingly vigorous, partly because of the availability of short-duration rice varieties and irrigated farming systems with multiple-cropping potential (Slayton, 2009). In Vietnam, for example, which has three distinct cropping seasons for rice, production increased by 6.3% in 2007 and by 5.3% in 2008, compared with average annual increases of just 3.3% per year between 2005 and 2011. All of this increase in production, a total of 1.2 mm, was put on the export market.

Countries can also hold emergency food stocks as part of a broader strategy for providing food security to their citizens. Expectations of higher and more volatile food prices in the future should lead authorities to invest in larger food stocks than in the past. The 'design rules' for adding to and disposing of these stocks, and their day-to-day management to avoid large storage losses, will be essential to making emergency food stocks a sustainable and cost-effective approach (Timmer, 2009c). Clear rules on management of public stocks minimize the displacement of private storage.

One critical element of these rules will be to use international trade in the commodity as part of the provisioning mechanism, thus avoiding the extraordinarily high costs that can come from a strategy of total self-sufficiency. Even in countries as large as Indonesia, India, and China, where a high degree of food self-sufficiency is required simply because of the limited size of world grain markets, some interaction with these markets through a managed trade regime can lower the costs of food security. Managed trade regimes can be open and transparent, with clear rules on the nature of interventions, thus allowing the private sector to handle actual trade logistics.

The third approach to coping with a food crisis is to provide safety nets to poor consumers, either in cash or through the direct provision of food aid. This was the immediate, and almost only, response of the donor community to the food crisis in 2007–08. The safety net approach figures prominently in 'best practice' recommendations from the World Bank, FAO, and the World Food Program (World Bank, 2005). The logic is clear: let high prices be reflected in local markets to signal the necessary changes in resource allocations to both producers and consumers, but protect the very poor from an irreversible deterioration in their food intake status. Efficiency is maintained, and the poor are protected.

The difficulty is that food crises are relatively short-lived events (as opposed to chronic poverty). Effective safety nets take a long time to design and implement, and they are very expensive if the targeted poor are a significant proportion of the population. Unless a well-targeted program with adequate fiscal support is already in place when the crisis hits, it is virtually impossible for a country to design and implement one in time to reach the poor before high food prices threaten their nutritional status. Even when a program is in place, and can be scaled up quickly, as with the Raskin program of rice distribution to the poor in Indonesia, operational inefficiencies and simple corruption in deliveries may mean that the poor are reached only at exceptionally high cost (Olken, 2006).

Improving the Supply Outlook

A number of chapters in this Encyclopedia treat various dimensions of increasing agricultural output and food supply. The cursory discussion in this section focuses mostly on the challenges facing that task as they relate to food security. In keeping with the basic framework of the chapter, there are short-run and long-run dimensions, and issues at the micro, macro, and global level. Only the global and long-run topics are treated here.

The long-run issue is whether supply responses can meet the outlook for rapid growth in demand, especially at the global level (although this will obviously be made up of varied national responses). In the past, when food prices spiked and talk of an impending Malthusian crisis arose, output responded to bring world food prices back to their long-run downward trend, though with a lag. Now, expectations are that such a benign output response may not be forthcoming, for three basic reasons: limited land available for expanding area; stagnant yields; and high-cost inputs.

A quarter of a century ago Hayami and Ruttan (1985) pointed out that area expansion as a source of increased agricultural production was drawing to a close, with future increases needing to come from higher yields on existing farmland. More than a decade into the twenty-first century, it is clear that there is little high-quality, unutilized agricultural land now available for farming. Even existing agricultural land is under threat in many regions from overexploitation and degradation, expanding recreational use, urbanization, even speculative demand from investment funds. Where there is good land available for expansion, especially in Africa and a few areas in Southeast Asia, vigorous competition, especially from foreign companies and sovereign investment funds ('land grabs'), is making that land inaccessible to local farmers.

Yields at research stations of existing agricultural technologies have essentially been unchanged for decades because of the paucity of investment in research during this time. Thus raising yields from actual farmer practices to the present technology potential is the only source of increased output until new agricultural technologies are developed. New technologies, however, are at least a decade away. Moreover, the yield gap to full potential has largely been closed except for Africa.

The costs of essential inputs – fuel, fertilizer, and water – to obtain greater yields are both high and growing rapidly. In addition, prolonged periods of high grain prices are likely to raise land rents and rural labor costs.

Managing Demand: Biofuels and Food Policy

Biofuels are not new. Although coal was known in China in prehistoric times, and was traded in England as early as the thirteenth century, it was not used widely for industrial purposes until the seventeenth century. Until then, biofuels were virtually the only source of energy for human economic activities, and for many poor people they remain so today. However, the widespread use of fossil fuels since the Industrial Revolution has provided a huge subsidy to modern economic activities as coal and later petroleum were so cheap – a subsidy which seems to be nearing an end.

The role of biofuels going forward, and the impact on agriculture, will depend on the structure of agriculture in individual countries. In the extreme, the demand for biofuels in rich countries to power their automobiles has the potential to raise the price of basic agricultural commodities to such a level that the entire structural transformation could be reversed. If so, the growing use of biofuels has two alternative futures: it could spell impoverishment for much of the world's population because of the resulting high food prices, or it could spell dynamism for rural economies and the eventual end of rural poverty. Which future turns out to be the case depends fundamentally on the location, technology, economics, and politics of biofuel production (and whether new energy sources and technologies, such as cheap natural gas or more efficient batteries to store solar and wind energy, come on stream).

The potential devastating effects of biofuels are easy to conceptualize (Naylor, 2012). The income elasticity of demand for starchy staples (cereals and root crops for direct human consumption) is less than 0.2 on average, and falling with higher incomes – it is already negative in much of Asia. Adding in the indirect demand from grain-fed livestock products brings the average income elasticity to approximately 0.5, and this is holding steady in the face of rapid economic growth in India and China. Potential supply growth seems capable of managing this growth in demand.

However, the demand for biofuels is almost insatiable in relation to the base of production of staple foods. The income elasticity of demand for liquid fuels for automobile and truck fleets, not to mention power generation, is greater than one in developing countries. The average for the world is rising as middle class consumers in China, India, and beyond seek to graduate from bicycles to motorbikes to automobiles. One simple calculation shows the dimension of the problem: if all the corn produced in the US were used for ethanol to fuel automobiles, it would replace just 15% of current gasoline consumption in the US. Something has got to give.

If this were a market-driven process, it is easy to see what will give. High grain prices will make ethanol production uneconomic, driving down the demand (and returns on investments in ethanol processing plants). Greater profitability of grain production will stimulate a supply response, although this may take several years if improved technologies are needed. Grain prices will reach a new equilibrium, with demand from the biofuel industry having only a modest impact.

This is not the scenario most analysts see. Instead, political mandates to expand biofuel production in many countries will continue to drive investments in processing facilities and the need to keep these profitable in the face of high raw material prices will require large public subsidies. Rich countries will be able to afford these more easily than poor countries, so a combination of inelastic demand for fuel and a willingness to pay large subsidies will keep grain prices very high (Naylor, 2012; de Gorter and Just, 2010).

If this scenario plays out, the consequences for economic growth, poverty reduction, and food security in developing countries depends on the role of agriculture in individual countries, the pattern of commodity production, and the distribution of rural assets, especially land. It is certainly possible to see circumstances where small farmers respond to higher grain prices by increasing output and reaping higher incomes. These incomes might be spent in the local, rural nonfarm economy, stimulating investments and raising wages for nonfarm workers. In such environments, higher grain prices could stimulate an upward spiral of prosperity.

An alternative scenario seems more likely however, partly because the role of small farmers has been under so much pressure in the past several decades. If only large farmers are able to reap the benefits of higher grain prices, and their profits do not stimulate a dynamic rural economy, a downward spiral can start for the poor. High food prices cut their food intake, children are sent to work instead of school and an intergenerational poverty trap develops. If the poor are numerous enough, the entire economy is threatened, and the structural transformation comes to a halt. The share of agriculture in both employment and GDP starts to rise, and this reversal condemns future generations to lower living standards. There will be much more 'structural' poverty, and countries determined to cope with it will find themselves supporting expensive and long-term safety nets for the poor.

A reversal of the structural transformation as the regular path to economic development and reduced poverty will be a historical event, countering the patterns generated by market forces over the past several centuries. Such an event is likely to have stark political consequences, as populations do not face the sustained prospect of lower living standards with equanimity. It is possible, of course, that new technologies will come onstream and lower energy costs across the board and thus allow the biofuel dilemma to disappear quietly – the natural gas revolution in the US certainly holds significant potential. However, it looks like a rocky couple of decades before renewable energies are available and competitive with fossil fuels.

A Food Policy Response to Climate Change

The biofuel challenge to food policy analysts stems from efforts to mitigate climate change. Equally challenging will be efforts to adapt agriculture to the dual effects of climate change – higher temperatures and greater variability in rainfall. In pulling together their final thoughts on the impact of climate change on food availability, food access, and food utilization – the three main factors that determine food security – Lobell and Burke make the following observation:

> …one thing appears almost certainly true in the twenty-first century; if agriculture and food security are to thrive, they will have to do so in a constantly warming world. The level of climate stability that has been experienced since the dawn of agriculture is a thing of the past; the future will be one of constant change. This need not spell disaster for food security, but we would be wise not to underestimate the enormity of the challenge at hand (Lobell and Burke, 2010, p. 1960).

Food policy analysis that understands this challenge and offers insights into how best to cope with it will be a key driver of how successfully society adapts to climate change.

Behavioral Dimensions to Food Security

Perhaps the most important element of food security in the minds of most citizens is the fear of a food crisis, when prices spike or staple foods (especially rice) disappear from the

market. Accordingly, preventing food crises through better understanding of their fundamental causes, thus allowing implementation of better food policies, should be a high priority for food policy analysts. Once a food crisis hits, coping with its consequences becomes the main task at hand, with emergency food aid and other forms of safety nets hastily brought into play. However, preventing food crises in the first place, especially by preventing sharp spikes in food prices, is obviously a superior alternative if a way can be found to do it. Understanding the behavioral dimensions of food security is an important step in learning how to prevent food crises. New insights from behavioral economics explain why governments should stabilize basic food grain prices (Timmer, 2012). With a better understanding of 'why,' it is possible to suggest better approaches to 'how.'

It is conceptually possible to hedge the risks from unstable food prices, or to mitigate their welfare consequences for the poor using safety nets, but there are no markets in which to purchase stability in food prices directly. The message is clear. Citizens would willingly go to the market to buy food price stability, but such a market does not exist, no doubt because the private coordination costs are too high. Food price stability is a public good, not a market good. Understandably then, citizens turn to the political market instead, although the costs of providing price stability as a public sector activity can also be very high, especially if public food agencies are poorly managed and become highly corrupt. However, only political action and public response from governments can provide stable food prices. Thus, food becomes a political commodity, not just an economic commodity, and a 'behavioral political economy' is needed to understand how food policy can achieve and sustain food security.

Understanding the behavioral foundations of formation of price expectations will be critical to building this new political economy. In particular, the dynamics of herd behavior and the tendency of bad news – about terrorism, wild fires, or a sudden rise in rice prices in local markets – to serve as a 'focusing event' in stimulating simultaneous, spontaneous behavior that results in panics, provide robust insights into how individuals form price expectations and respond to them (Tversky and Kahneman, 1986).

Governments that fail to stabilize food prices have failed in the provision of a quite basic human need that is rooted in behavioral psychology – the need for a stable environment. Governments that are successful in stabilizing food prices are usually rewarded politically; witness the landslide victories of Prime Minister Manmohan Singh in India and of President Yudhoyono in Indonesia in early 2009. Both candidates campaigned openly on their ability to bring their countries through the world food crisis with minimal impact on domestic food prices. Clearly, other factors contributed to the electoral success in both countries, but it is equally clear that the governments' abilities to provide stable food prices when the rest of the world was experiencing a food crisis were politically popular.

The trick, of course, is to provide stability in domestic food prices at low cost to economic growth, participation by the poor, and government finances. By and large, Asia has figured out how to do this as a domestic endeavor, but with large negative spillovers to world markets (Timmer, 2009c). African countries do not have a viable strategy for stabilizing their domestic food prices, and the continent suffers even more from the instability in world markets transmitted from the Asian approach to food price stabilization (Jayne, 2009). Indeed, the resource riches of Africa are attracting sizable investments from Asia (and elsewhere), but there seems to be little linkage between these investments, especially in land to produce food crops for export, and local food security.

The food security challenge is thus twofold: (1) to help Asia find more efficient ways to stabilize their domestic food prices, especially for rice, with fewer spillovers to world markets (and now including investment spillovers as well as price spillovers) and (2) to help Africa find a way to stabilize their domestic food prices without introducing serious distortions to their food economies or retarding the development of an efficient private food marketing sector. Neither of these challenges can be met without a basic rethinking of development approaches by academics, government policy circles, NGOs and community leaders, and citizens themselves. Ending hunger is hard because it is so complicated, deeply entwined with how we organize economic activities and regulate them through public policies. However, it is not impossible either, with better understanding of these complications and concerted efforts to resolve them.

Food Security: Postharvest Losses

MC Bourne, Cornell University, Geneva, NY, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Relative humidity The ratio of the amount of water vapor present in the air expressed as percent of the greatest amount possible (saturation) at the same temperature.

Introduction

There are two kinds of food security that require completely different approaches to resolution:

Type 1: Postharvest loss covers the technologies needed to preserve food in safe and edible condition between the time of harvest and the moment it is prepared for consumption by people. The time can range from minutes to years. It is the subject of this article.
Type 2: Food biosecurity or food defense describes intentional contamination or destruction of the food system for warfare, political coercion, unfair economic gain, or exacting revenge. This topic will be covered in the accompanying article by N. Fredrickson.

The world production of food is enormous and the amount increases every year because of great efforts by many in the agricultural production sector. Some illustrative data are given in Table 1, which lists worldwide production of the major foods in 1989 and 2009.

This is sufficient to provide 100% of the nutritional requirements of every living human being.

It needs to be pointed out that the data in Table 1 lists production, not consumption. A substantial portion of the foods listed in Table 1 is not consumed because it is lost or becomes unfit to eat after harvest. These are known as 'postharvest food losses.'

Another aspect of world food production statistics is that the production is not evenly distributed among populations.

Table 1 World production of major foods 1989 and 2009

World food production (million tons) in 1989 and 2009		
Year	*1989*	*2009*
Cereals	1880	2489
Starchy roots and tubers	599	753
Vegetables	438	941
Fruits	345	588
Cow milk	471	697
Beef and buffalo	52	62
Pork	68	106
Eggs	36	67

Rome: Food and Agriculture Organization of United Nations. Available at http://www.fao.org/docrep/015/am081m/am081m00.htm (accessed 29.10.13).

Developed countries have abundant food at reasonable cost. It is easy for their people to overeat, which leads to obesity and associated medical problems such as high blood pressure, diabetes, and coronary heart disease. In these countries large quantities of good edible food are discarded because of the demands for convenience and perfect appearance. These losses are defined as 'food waste.' In contrast most developing countries have insufficient food and food is high in cost in relation to income. Their problem is undernutrition, which leads to stunted growth, impaired ability to fight infectious diseases and starvation. There are approximately a billion people in this category. Families in developed countries typically spend 15–25% of their income on food whereas families in developing countries (DCs) spend 50–80% of their income on food. In DCs a food loss is a huge economic blow whereas in a developed country wasting food has a trivial cost. Insufficient food and high cost of food is a major contribution to the elevated rate of morbidity and mortality in developing countries.

The publication '2012 Global Hunger Index' jointly produced by The International Food Policy Research Institute in Washington, DC, Welt Hunger Hilfe in Bonn and Concern Worldwide in Dublin describes in detail the severity of hunger around the world (http://www.ifpri.org/publication/2012-global-hunger-index). A brief history of the development of postharvest food loss reduction activities can be found in Bourne, 2013.

Increasing Food Supply

The projected increases in the world population in the next 50 years means that there must be concomitant growth in food production. There are four main avenues by which the supply of food can be increased:

1. Increase the area of production: This includes activities such as clearing and developing new land, introduction of irrigation systems, developing salt-tolerant cultivars of crops, etc.
2. Increase the yield of crops harvested per unit area: This includes activities such as the development of higher-yielding cultivars, greater use of fertilizers, breeding plants and animals that are resistant to diseases, and controlling field losses resulting from insects, rusts, and rodents.
3. Produce more crops per year: Multiple cropping systems in which several crops per annum are harvested are activities that can be utilized where length of growing season and water availability are suitable.

 doi:10.1016/B978-0-444-52512-3.00035-8

4. Reduce postharvest loss and waste: It is wasted effort to increase food production if this increase does not fulfill its nutritional destiny by getting into the stomach. This fourth avenue to increase food availability has never received the attention and resources that have been directed to the first three items mentioned above. Spurgeon (1976) has aptly called the reduction of postharvest food losses the 'hidden harvest.' This fourth avenue is a less obvious strategy than increasing production but it is an essential, and often overlooked part of ameliorating hunger in the world.

There are good reasons to concentrate on increasing food production because these avenues have an 'open-end' potential – increases of 50%, 100%, or more are possible. In contrast, postharvest food loss reduction has a 'closed-end' potential. For example, if postharvest losses are 15% then the maximum increase that can be obtained from this avenue is 15%. Although this may seem to be a small item, it carries more weight than appears at first sight as the formula to calculate the increase in production needed to affect a postharvest food loss shows:

$$\text{Production increase needed to offset postharvest loss} = \text{amount of consumable grain} \times \frac{100\%}{100 - \%\ \text{postharvest loss}}$$

Suppose 100 tons of grain are harvested and there is a loss of 20 tons (20%) in the postharvest system. There are two ways to regain 100 tons of consumable grain:

1. Eliminate the 20% postharvest loss.
2. Increase production to 125 tons (a 25% increase) so that after losing 20% of the 125 tons there will remain 100 tons for consumption. In other words, it requires a 25% increase in production to offset a 20% postharvest loss. Similarly, it would require a 100% increase in production to offset a 50% postharvest loss.

Some Definitions

It is necessary to precisely define what is meant by the term 'postharvest food loss' in order to prevent confusion and to establish boundaries so the term does not cover every aspect of the food chain. The following three-part definition from Bourne (1977) has been widely used.

'Postharvest' means after separation from the medium and site of immediate growth or production of the food.

Postharvest begins when the process of collecting or separating food of edible quality from its site of immediate production has been completed. The food need not be removed any great distance from the harvest site, but it must be separated from the medium that produced it by a deliberate human act with the intention of starting it on its journey to the table. The postharvest time ends when the food enters the mouth; it does not cover inefficiencies in human metabolism and utilization of the food.

'Food' means wholesome edible material that would normally be consumed by humans.

Inedible portions such as hulls, stalks, leaves, skins, bones, and shells are not food. Two critical nutrients, oxygen and water, are excluded because they are normally not considered as foods. Potential food (e.g., mycoprotein or leaf protein) are not foods; they do not become food until they are accepted and consumed by large populations. Feed (intended for consumption by animals) is not food. Crops grown for fuel production are not food. The method of measuring the quantity of food in the postharvest chain should be on the basis of weight expressed on a moisture-free basis or a specified moisture basis because changes in moisture content are not a food loss or food gain. For example, if 100 tons of rice at 20% moisture is dried to 90 tons at 10% moisture there is no food loss because only water is lost.

There will be times when information on losses in nutritional units and economic losses will also be needed but these are not the primary means of measuring postharvest food losses.

'Loss' means any change in the availability, edibility, wholesomeness, or quality of the food that prevents it from being consumed by people.

Food losses may be direct or indirect. A direct loss is disappearance of food by spillage, or consumption by rodents or birds. An indirect loss is the lowering of quality to the point where people refuse to eat it. If the food is consumed by people it is not lost; if it is not consumed by people for any reason at all then it is considered a postharvest food loss.

'Food waste' was originally defined as edible material intended for human consumption, arising at any point in the food supply chain that is instead discarded, lost, degraded, or consumed by pests (FAO, 1981). Over the past decade or so the term 'food waste' has come to mean wholesome edible food that is thrown out because of consumer demand for perfect appearance and convenience. This has become a problem in affluent countries where the cost of food in relation to income is low and people can afford to discard wholesome food if they are sated or it does not meet their high expectations for appearance, texture, or flavor. This meaning is in contrast to food loss, which means the food is unavailable or has become unfit to eat. A 2011 report from FAO gives extensive data on food loss and food waste (FAO, 2011). It shows that food waste is high and food loss low in developed countries whereas food waste is low and food loss is high in developing countries.

The motivation to reduce food waste is to reduce stress on the environment and requires a modification of human behavior. In contrast, reducing food loss requires the application of food preservation technologies and the motivation is to bring more food to those who are malnourished and poor. This article addresses the problems of food loss and how to reduce them. It will not address the problems of food waste and their reduction. Recent articles addressing food waste can be found in Parfitt *et al.* (2010), Gunders (2012), Beddington *et al.* (2012), and Institution of Mechanical Engineers (2013).

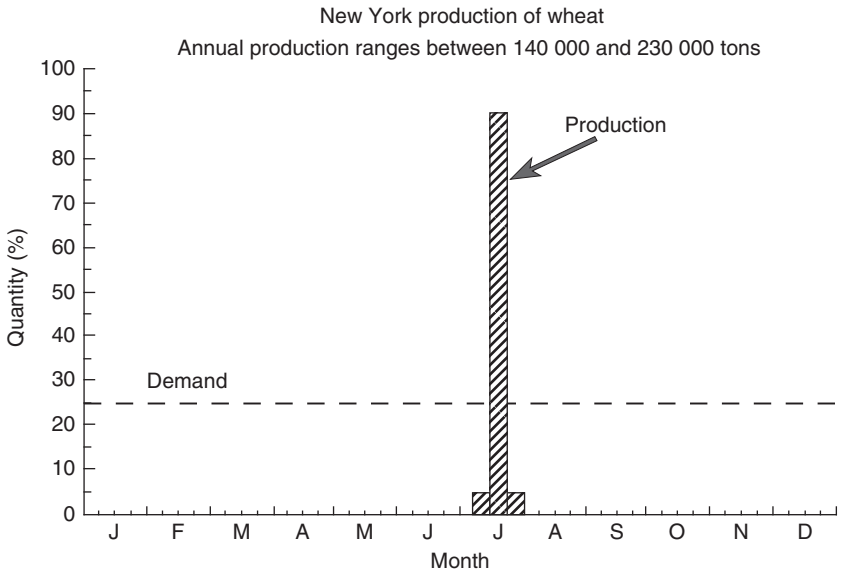

Figure 1 Production of wheat in New York state – a year's supply is harvested in a 3-week period.

Nature of the Problem

Within a given region the daily demand for food is constant over the course of a year (excluding any changes in population) but the supply of food for that region is very uneven from day to day over the course of the year. Food preservation, storage, and transportation are the mechanisms by which humankind matches the uneven day-to-day supply of food with the even day-to-day demand for food. This problem of matching the uneven food supply to the even demand has been a problem throughout recorded history.

The problem is that although humankind grows or hunts food for their own personal consumption, there are many other living organisms that try to use this food. This includes organisms ranging from large animals, through small forms of life such as insects down to microscopic forms of life such as bacteria. These produce direct losses – the food is no longer there.

Moreover, there is a natural tendency for food, which is built up principally from inorganic carbon, nitrogen, and water sources into complex energy-rich organic compounds, to degrade again to the simple inorganic compounds from which it was produced in the first place. These biochemical and chemical reactions occur spontaneously and lower the quality of the food. These produce indirect losses – the food is no longer fit to eat.

These problems are illustrated in Figure 1, which shows the production of wheat in New York State for each month of the year. The farms in New York produce no wheat from January to June or from August to December. All the wheat is harvested in the month of July as shown by the vertical bars. In fact, 90% of the wheat is harvested in 1 week, usually the third week of July. However, the demand for bread, macaroni, donuts, and all other nice foods made from wheat is very uniform throughout the year as shown by the dashed line parallel to the horizontal axis of Figure 1.

Most of the world food supply is seasonal – cereals, legumes, fruits, vegetables, roots, and tubers produce a large crop over a short period of time and then nothing until the next crop matures. The time when the harvest is ready can be any month of the year depending on the climate and nature of the crop but the pattern of a large harvest followed by a period of no harvest is the common feature. In some locations, where climate and water supply permit there is more than one harvest per year. In those cases there are two or more peaks of production with nothing in between.

Foods obtained from domestic animals are not seasonal. With good management, the time of harvest can be controlled to become uniform throughout the year. Milk and eggs can be harvested daily. Animals and birds can be kept alive and slaughtered as needed. Some fish harvests are seasonal because wild fish cannot be managed like domestic animals. Therefore, apart from fish, foods of animal origin are not given attention in postharvest loss reduction programs (but they do receive a lot of attention in food waste prevention programs).

Causes of Losses

There are many causes of postharvest food losses and they can be grouped under the headings of primary and secondary causes. Examples of loss are given for each cause.

Primary Causes

1. Biological and microbiological: Consumption or damage by insects, mites, rodents, birds, larger animals, and by microbes such as fungi and bacteria.
2. Chemical and biochemical: Undesirable reactions between chemical compounds that are present in the food such as the Maillard reaction, fat oxidation, and enzyme-activated reactions; contamination with harmful substances such as pesticides, or obnoxious substances such as lubricating oil.
3. Mechanical: Spillage, abrasion, bruising, excessive polishing, peeling or trimming, puncturing of containers, defective seals on cans, or other containers.

4. Physical: Excessive or insufficient heat or cold, improper atmosphere.
5. Physiological: Sprouting of grains and tubers, senescence in fruits and vegetables, and changes caused by respiration and transpiration.
6. Psychological: Human aversion, such as "I don't fancy eating that today." This is the major cause of food waste, but is a minor cause of food loss.

Some of the causes of losses interact. For example, respiration generates heat which if not dissipated will accelerate biochemical and chemical changes. If the temperature continues to rise the point is reached in stored grain where the grain blackens and eventually burns (spontaneous combustion).

In some cases more than one of these causes may be responsible for food loss. Multiple causes may work simultaneously or sequentially. Simultaneous action is the growth of mold and insects at the same time. An example of sequential action would be first the growth of mold which is stopped by drying, followed by biochemical reaction caused by the enzymes elaborated by the mold that results in unacceptably soft texture, rancid flavor, or inferior color.

Secondary Causes

Secondary causes lead to conditions that enable a primary cause of loss to occur. These usually are the result of inadequate human input. Examples include

1. inadequate drying equipment or poor drying season;
2. inadequate storage facilities to protect food from insects, rodents, birds, rain, and high humidity;
3. inadequate transportation to get the food to market before it spoils;
4. inadequate refrigerated or frozen storage (for perishables);
5. marketing system that fails to connect potential buyers with producers; and
6. legislation: The presence or absence of legal standards can affect the eventual retention or rejection of a food for human use.

There are times where it is possible to use a primary cause to offset a secondary cause and vice versa. For example, the problem of a poor transportation system can be partially overcome by drying of grain so that it does not become moldy so quickly, or by growing a variety of a tuber that has longer keeping properties. Conversely, insufficiently dried grain can be rushed to market and sold before it molds if good transportation and marketing services are available.

Cause – Commodity Link

The causes of food loss depend on the type of food, which are summarized below:

Cereals – fungi, insects, vertebrate pests, and poor milling.
Fruits and vegetables – bruising, rotting, senescence, and wilting.
Roots and tubers – sprouting, rotting, senescence, and wilting, insects.
Meat, milk, poultry, and fish – growth of microbes.
Dry fish – fungi and insects.

Food preservation technologies that control each of these causes of food loss are well known in developed countries. Unfortunately, the technologies are not so well known in developing countries nor are the equipments for storage, transport, and handling facilities readily available and reasonable in cost. Societies that suffer the worst hunger and malnutrition are the ones with the least knowledge of food preservation technologies and have the poorest infrastructure to preserve their food.

Factors Affecting Losses

Nature of the Product

Moisture content

Foods with high-moisture content (fruit, vegetables, foods of animal origin) generally have higher perishability and suffer higher losses than foods with a lower moisture content (e.g., cereal grains)

Texture

Hard items such as cereal grains do not bruise easily whereas soft items do bruise easily (mangoes, peaches). Items with a tough or thick outer skin (coconut, grapefruit) are more resistant to invasion by rotting organisms than those with a thin or tender skin (tomatoes, plums). Brittle foods fracture more easily than nonbrittle foods. For example, wheat at 25% moisture is somewhat pliable and does not fracture easily during handling but when dried to 10% moisture it becomes brittle and fractures easily.

Respiration rate

Much of our food is still living when harvested and, therefore, respiring by absorbing oxygen from the surrounding air and giving off carbon dioxide and water vapor. High respiration rates shorten shelf life. For example, asparagus (respiration rate at 9700 BTU ton^{-1} day^{-1} at 0 °C and 49 000 BTU ton^{-1} day^{-1} at 21 °C) has a much shorter shelf life than onion (respiration rate 650 BTU ton^{-1} day^{-1} at 0 °C and 3650 BTU ton^{-1} day^{-1} at 21 °C) (see Table 2).

Table 2 Heat generation vs. storage temperature for some fruits and vegetables

Heat generation by fresh fruits and vegetable (B.T.U. per ton per day)

	0 °C	*5 °C*	*15 °C*	*21 °C*	*27 °C*
Apples	700	1 350	4 900	5 700	–
Asparagus	9 700	18 000	39 000	49 000	92 000
Lettuce	2 500	3 650	8 500	12 200	18 100
Cantaloupes	1 200	2 100	7 900	12 000	14 700
Onions	650	750	2 400	3 650	6 200
Green peas (shelled)	13 500	19 400	–	99 500	–

Source: Reproduced from Hardenburg, R.E., Watada, A.E., Wang, C.Y., 1986. The commercial storage of fruits, vegetables, and flowers and nursery stock. US Department of Agriculture Handbook Number 66. Washington, DC: United States Department of Agriculture.

Table 3 Comparison of cereals with horticultural crops

Comparison of horticultural crops vs. cereals	
Cereals and oilseeds	*Horticultural crops*
Low moisture content, typically 10–15%	High-moisture content, typically 80–95%
Small unit size, typically less than 1 g	Large unit size, typically from 5 g to 10 Kg
Very low respiration rate with very small generation of heat. Heat production, typically 0.05 MJ ton^{-1} day^{-1} for dry grain	High to very high respiration rate. Heat production, typically 0.5–10 MJ ton^{-1} day^{-1} at 0 °C and 5–70 MJ ton^{-1} day^{-1} at 20 °C
Hard texture	Soft texture, easily bruised
Stable, natural shelf life, several years	Perishable, natural shelf life, several days to several months
Losses usually caused by molds, insects, and rodents	Losses usually caused by senescence, sprouting, rotting (bacteria and fungi), and bruising
Losses in DCs usually 10–20%	Losses in DCs usually 15–50%

Cereals have a very low respiration rate. However, the respiration of mold or insects within the grain mass releases carbon dioxide, water vapor, and heat which can damage the grain quality. Table 3 summarizes differences between cereal grains and horticultural crops.

Perishability

The inherent perishability of food as harvested determines what technologies are needed to maintain it in excellent condition. Perishable foods are prone to higher losses than stable foods. The level of perishability can be assigned to three levels:

- Highly perishable foods remain in edible condition for a few hours to a week unless some preservation technology is promptly applied. Foods such as milk, meat, fish, poultry, and some fruits and vegetables fall into this class.
- Perishable foods remain in edible condition for a week to several months unless treated. Some fruits and vegetables, tubers and roots, and oils are in this class.
- Stable foods remain in edible condition for several months to many years. This class includes cereal grains, oilseeds, many nuts, and honey.

Preservation technologies stabilize, safeguard, and maintain the harvest from land and sea in a condition suitable and safe for human consumption. The technologies selected for any food depend on the level of perishability and how much extension of shelf life is required. Refrigeration and pasteurization bring highly perishable foods into the perishable class whereas freezing, dehydration, and thermal sterilization enable them to be kept for months or years. Similarly, refrigeration, controlled or modified atmosphere storage, and chemical preservatives convert perishable foods into stable forms.

Processing technologies convert edible food materials into another form with higher acceptability and they usually make the food more perishable. For example, wheat is stable and keeps for years but when made into flour it becomes a perishable product because of oxidation. However, when flour is made into bread it becomes highly perishable because of staling and/or molding. However, bread can be changed from highly perishable to perishable by including preservatives and antistaling agents, or even back to stable condition by freezing. Similarly, barley is stable but when made into beer it becomes highly perishable. Refrigerating beer moves it from highly perishable to perishable.

Changes in perishability are shown schematically in Figure 2, where preservation technologies shown by the arrows on the left side decrease perishability and many processing technologies shown by the arrows on the right side increase perishability.

Climate

Temperature

During storage changes in food may be caused by

- microbial action (yeasts, fungi, bacteria);
- chemical reactions within the food (fat oxidation, browning);
- biochemical reactions from enzyme activities;
- physiological changes (respiration, sprouting); and
- biological agents (insects, rodents, birds).

All of these cause deterioration of quality (appearance, flavor, texture, nutritional value) and sometimes complete loss of the food. Most of these deteriorative changes occur at a faster rate as the temperature increases.

Example 1

Microbial growth: Table 4 shows the effect of temperature on the rate of increase in the number of bacteria in unpasteurized milk. At 0 °C the total count slowly decreases. The count increases at all temperatures above zero until at 30 °C (a normal day in a tropical country) the count becomes enormous within 24 h.

Example 2

Chemical reactions: Most foods naturally contain hundreds of different chemical components, most of which have reactive groups such as alcohols (–OH), aldehydes (–CHO), amines ($–NH_2$), carboxylic acids (–COOH), ketones (–CO), thiols (–SH), and double bonds (=). These allow numerous chemical reactions to occur many of which are not well understood but the rate of these reactions accelerates as the temperature increases.

The Q10 factor expresses the rate of change of a chemical reaction caused by a 10 °C increase in temperature. Chemical reactions performed in the chemistry laboratory frequently have a Q10 of approximately 2, that is, a 10 °C increase in

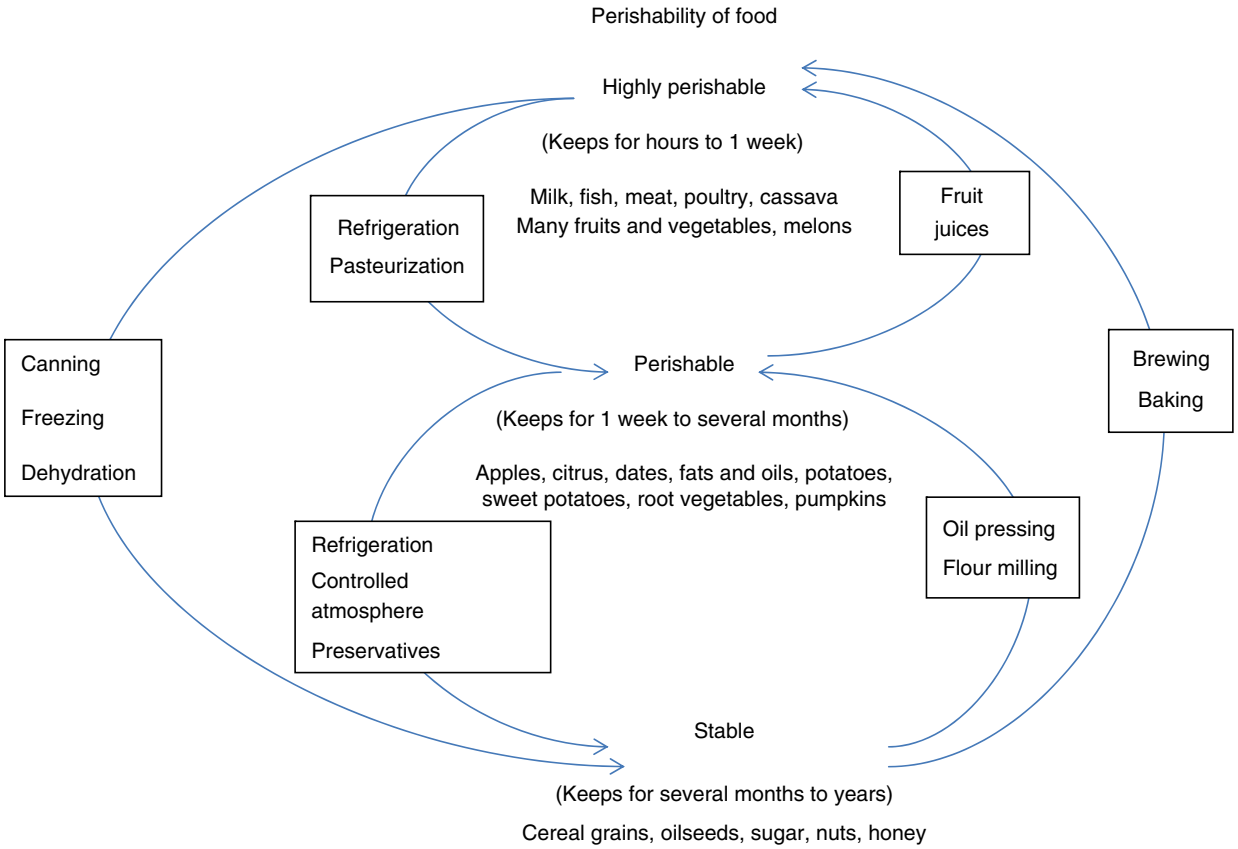

Figure 2 Levels of perishability in foods and changes caused by preservation technologies (LHS arrows) and processing technologies (RHS arrows).

Table 4 Growth of bacteria in unpasteurized milk

Growth of bacteria in unpasteurized milk (number of organisms per milliliter of milk)

Temperature (°C)	*24 h*	*48 h*	*96 h*	*168 h*
0	2 400	2 100	1 850	1 400
4	2 500	3 600	218 000	4 200 000

30	1 400 000 000	–	–	–

Source: Personal communication from F. Shipe.

temperature will double the rate of the chemical reaction. Chemical reactions occurring in foods usually have a higher Q10 in the 3–8 range. That is, a 10 °C increase in storage temperature will increase the rate of the chemical reactions that are spontaneously occurring three-fold to eight-fold.

A more fundamental description of the effect of temperature on reaction rates is the Arrhenius equation:

$$\log_{10} K = A - \frac{Ea}{4.6T}$$

where K equals the rate constant, A equals a constant, Ea equals the activation energy, and T equals the absolute temperature in Kelvin A Q10 factor of 10 is equal to Ea 12 800 cal mol^{-1}. Activation energies for reactions in food are often much higher than 12 800 cal mol^{-1}. The accepted rule that chemical reaction rates double for every 10 °C in temperature usually underestimates the rate of loss caused by deteriorative chemical reactions in foods. Even a small increase in temperature will markedly increase the rate of most deteriorative chemical reactions in foods.

Figure 3 shows the rate of nonenzymatic browning of freeze-dried onion measured as the absorbance of a water extract measured in a spectrophotometer. Onion stored at 5 °C showed no browning after 160 days whereas onion stored at 45 °C showed considerable browning.

Figure 4 shows the loss of thiamine in canned meats stored for 3 years at 0 °F (−18 °C), 32 °F (0 °C), 70 °F (21 °C), and

100 °F (38 °C). Note how much faster thiamine and sensory quality are lost as the storage temperature increases.

Example 3

Arthropods (insects): Table 5 shows the minimum, optimum, and maximum growth temperature for insects commonly found in stored food. None of these insects grow below 15 °C (except mites) and the optimum temperatures are typical of the temperatures found in the tropics.

To sum up

- High storage temperatures accelerate most deteriorative changes that occur in stored food. Even stable foods such as cereal grains deteriorate more quickly as the temperature increases.
- Hence, tropical zones have a more difficult problem in maintaining food quality than do temperate zones. Arctic zones have little problem with food spoilage other than freezing injury. The rapid growth of plants in the humid tropics is matched by a rapid rate of decay.
- Shelf life for all foods is shorter in the tropics than in the temperate zones. One cannot expect to get as long a shelf life in a hot climate as in a cold climate.
- All foods, even stable foods, should be stored in the coolest place possible. Always store away from heat such as direct rays of sun, near boilers, or cooking stoves.

Exposing foods or storage structures to direct sunlight increases the temperature and the activity of all spoilage vectors. In temperate climates, most foods are stored out of the sun. In contrast, in tropical climates one often sees food products exposed to the sun. Figure 5 shows the effect of exposing vegetables to direct sunlight all day in Geneva, NY (latitude 42°53′ N, longitude 77°02′W, elevation 220 m). Single whole vegetables were supported on a thin wire mesh raised 60 cm off the ground on a wooden frame and the temperature measured by copper–constantan thermocouples inserted into the geometric center of each item. The experiment was conducted in July; close to the time of the summer solstice when solar radiation is at its peak in the Northern Hemisphere although not as high as in tropical latitudes.

The ambient temperature was measured by the official weather station #3031840 of the US Department of

Table 5 Temperature requirements for growth of some stored product insects

Species	*Typical foodstuffs infested*	*Temperature for growth (°C)*		
		Minimum	*Optimum*	*Maximum*
Sitrotroga cerealella (Angoumous grain moth)	Whole cereals	16	32	35
Cadra cautella (tropical warehouse moth)	Cereals and oilseeds	15	30	38
Sitophilus oryzae (rice weevil)	Whole cereals	17	28	34

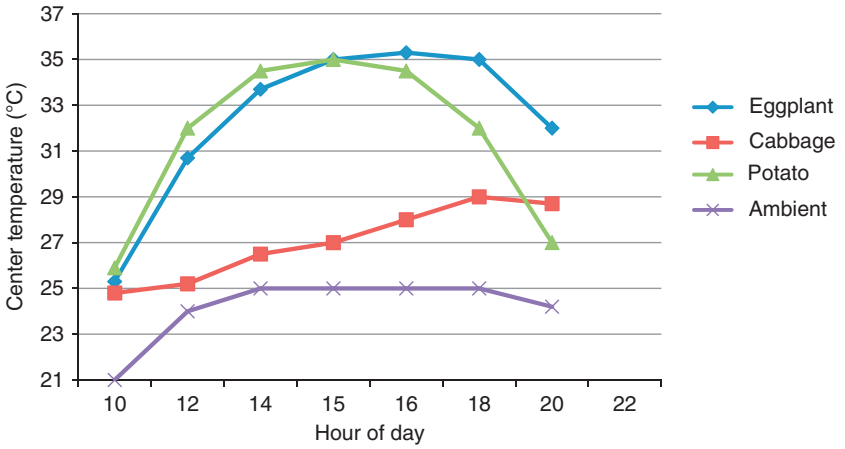

Figure 5 Internal temperature of three vegetables exposed to direct sunlight on a summer day. Reproduced with permission from Unpublished data of Marlett and Bourne.

Commerce National Oceanic and Administration Network and the temperature of the vegetables was measured approximately 1 m away from the weather station. The ambient temperature was at 21 °C at 10 am, rose to 25 °C in the middle of the day, and fell to 24 °C by 8 pm. Eggplant and potato had a dark skin and the internal temperature rose to 36 °C, some 12° higher than ambient. The temperature of the large head of pale-green cabbage rose to 29 °C.

Providing shade to food is a simple technology and should be universally used in developing countries. Comparing Figure 5 with the data in Table 2 shows that shade is effective in lowering the temperature and therefore the respiration rate thus extending the shelf life of the produce.

Climate data enable one to understand why food-spoilage rates are higher in some regions than in others and why it is more difficult to prevent losses in certain regions. Figure 6 shows the mean monthly temperature in three cities lying in the tropics and one city in a temperate zone. Medellin, Colombia, latitude 6° N, altitude 1498 m, has a mean monthly temperature of 22–23 °C all year long. From Table 5 one can expect to have problems controlling insects in stored grain throughout the year in Medellin. Panama, latitude 9° N, altitude 61 m, has a mean monthly temperature of 26–28 °C throughout the year and as this is close to the optimum temperature for insect growth one can expect to have more difficulty in controlling insects in stored grains than that in Medellin. In contrast, Bogota, Colombia, latitude 4.5° N elevation 2645 m, has a mean monthly temperature of 14–16 °C throughout the year and one can expect few problems with insects because it is too cold for insects to grow. These three cities lie in the tropics where there is little change in temperature throughout the year.

These three cities are relatively close together in the tropics. The differences in their temperature profile are caused by altitude. Ambient temperature decreases by approximately 5 °C for every 1000 m increase in altitude.

Cipoletti, Argentina, latitude 39° S, altitude 270 m, shows mean monthly temperatures typical of temperate climates; the monthly temperature is high in summer and low in winter. From Table 5 one can expect to have no problems with insects in stored grain from April through October when the temperature is below 15 °C, but insect problems can occur early (January

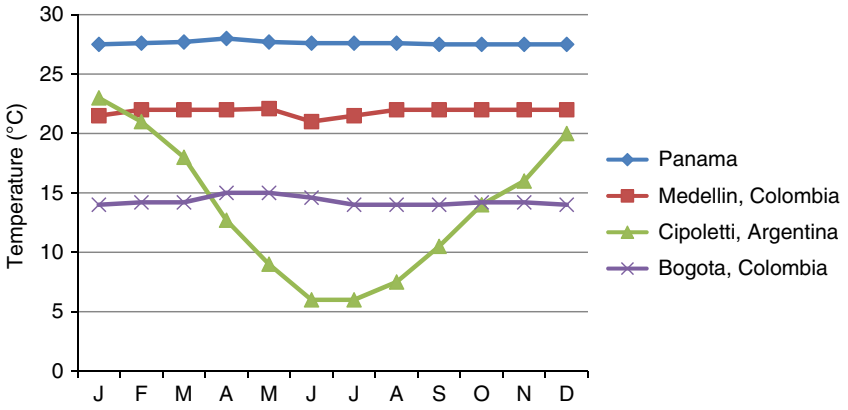

Figure 6 Mean monthly temperatures in Panama (latitude 9° N, elevation 61 m), Medellin (latitude 6° N, elevation 1498 m), Bogota (latitude 4.5° N, altitude 2645 m), and Cipoletti (latitude 39° S, altitude 270 m).

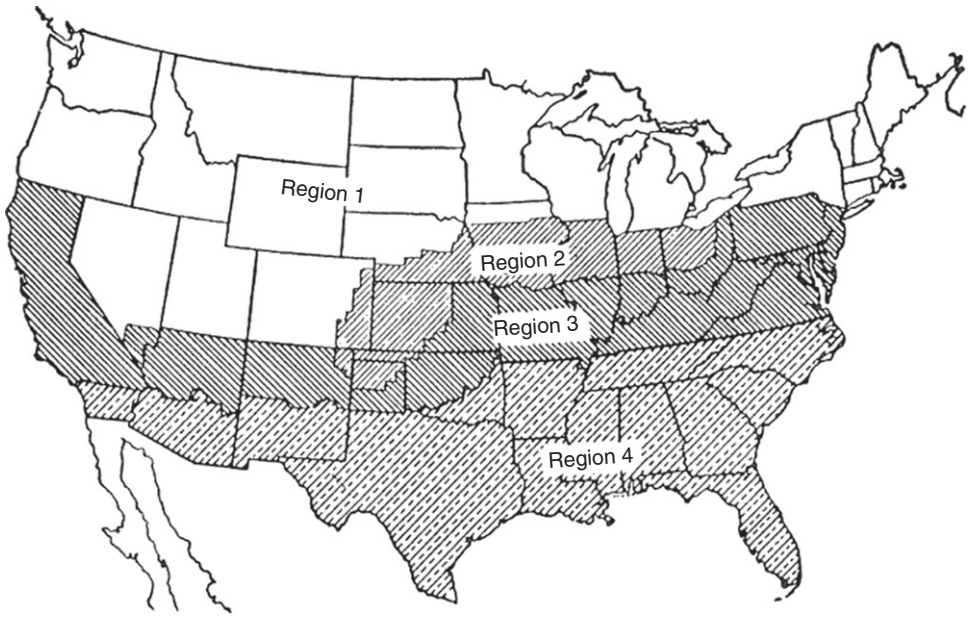

Figure 7 Stored grain risk across the US. Reproduced with permission from Cuperus, G., Noyes, R.T., Farg, W.S., *et al.*, 1993. Reducing pesticide use in wheat postharvest systems. Cereal Foods World 38, 199–203.

through March) and late (November through December) in the year when the ambient temperature is above 15 °C.

Figure 7 shows another example of the effect of temperature on storage stability of grains. Region 1 comprising northern states in the US has the lowest risk, and as one moves south into regions 2, 3, and 4 the risk increases as the average temperature rises. The dip in region 1 on the left side of the map is caused by the low temperatures experienced in the high mountains of the Sierra Nevada and the Rockies.

Relative humidity

Air always contains water vapor. It is usually expressed as the amount of water vapor in the air as a percentage of the amount that would be in the air if the air were saturated. The amount of water vapor at saturation increases as the temperature increases and many handbooks give tables for the saturation vapor pressure of water at different temperatures. The amount of moisture in any stored food will eventually equilibrate with the surrounding air. It is called the equilibrium relative humidity (ERH).

Dry foods are not sterile. They resist mold growth and other forms of microbial spoilage because their moisture content is too low to support growth. This statement applies to all dry foods – cereal grains, flours, spaghetti, dry fish, dry fruit, dry vegetables, dry milk, etc. The moisture content at which the foods begin to grow mold varies widely. For example, tea becomes moldy when its moisture content exceeds 7%, but unsalted dry fish does not mold until the moisture content exceeds 12%, whereas cereal grains will mold when moisture content exceeds 14%, and raisins do not mold until the moisture level exceeds 25%.

ERH, an old term, has been replaced by water activity (Aw), which is defined by the equation: Water activity $(\mathrm{Aw}) = \frac{P}{P_o}$; where P equals the water vapor pressure exerted by moisture in a food, P_o equals water vapor pressure exerted by pure water at

Table 6 Conditions for growth of some common fungi

Species	Temperature (°C)			Aw	
	Minimum	Optimum	Maximum	Minimum	Optimum
Aspergillus ruber	5	24	38	0.72	0.93
A. amstelodami	10	30	42	0.70	0.94
A. flavus	12	35	45	0.80	0.99
A. fumigatus	12	40	52	0.83	0.99
A. niger	10	35	45	0.77	0.99
Penicillium martensii	5	24	32	0.80	0.99

same temperature. For example, if a food has a water vapor pressure of 12.5 mm Hg at 20 °C, what is its water activity? Vapor pressure of pure water at 20 °C is 17.54 mm Hg (obtained from tables). Then $\text{Aw} = \frac{12.5}{17.54} = 0.71$.

The relationship between water activity and ERH is: $\text{Aw} = \frac{\text{ERH}}{100}$ or ERH = 100 Aw.

Example 1

If ERH is 71%, what is the water activity?

$$\text{Aw} = \frac{71}{100} = 0.71$$

Example 2

If water activity is 0.71, what is the ERH?

$$0.71 \times 100 = 71\%\ \text{ERH}$$

As Aw and ERH have the same numerical value it is easy to convert from one to the other; just move the decimal point two places. For a thorough description of water activity, consult any of the following references, Barbosa-Cánovas *et al.* (2007), Iglesias and Chirife (1982), or Bourne (1999).

The limiting water activity for most bacteria is approximately Aw = 0.90, for most yeasts approximately Aw = 0.88, for most molds (fungi) approximately Aw = 0.80, and for xerophilic molds Aw = 0.65. Conditions for growth of some common fungi are shown on the right-hand side in **Table 6**.

The moisture content of grains and other dried foods is such that there is seldom any problem with the growth of bacteria and yeasts but there are frequently problems with the growth of molds (fungi). Unless the Aw is reduced to below approximately 0.7, molds will grow on any food and as the relative humidity in the humid tropics is generally more than 70% almost all dry foods will become moldy when stored in the humid tropics unless the moisture content is reduced to an Aw of less than 0.70, followed by storage that will protect that food from absorbing moisture from the high-humidity environment.

Water vapor always moves from a region of high Aw to a region of low Aw until equilibrium is reached. Moist food will always give up water to dry air whereas dry food will always absorb moisture from high relative humidity air. The only way to prevent the invisible flow of water vapor from a high Aw region to a low Aw region is to place a barrier between the food and the air that will move through it. The design of storage structures for bulk commodities such as cereal grains, and packaging technologies for retail foods to prevent migration of water vapor are the subject of other articles in this encyclopedia.

Table 7 Moisture content for safe storage of paddy is inversely related to temperature

Water content – temperature – Aw for paddy rice		
Temperature (°C)	Aw	% H_2O (as-is)
7	0.70	14
27	0.70	13
43	0.70	12
57	0.70	11

Table 8 Moisture content and temperature effect on storage life of barley

Maximum number of weeks of mold-free storage of barley			
% H_2O	5 °C	15 °C	25 °C
16	>100	>100	10
18	80	12	2
20	9	3	1
22	4	1.5	0.5

Source: Personal communication from R. L. Obendorf.

As the saturation point of moisture in air increases with rising temperature, the safe moisture content for storage of grain becomes lower as the storage temperature increases. **Table 7** demonstrates how the moisture content of paddy rice needs to be reduced in order to maintain a safe Aw not greater than 0.70. Another example is that wheat with 14.0% water has an Aw equal to 0.75 at 30 °C and will mold, whereas the same wheat stored at 10 °C has an Aw equal to 0.68 and will not mold.

Table 8 shows how temperature and moisture content affect the safe storage life of barley.

There are two ways to express moisture content:

1. Wet basis or 'as-is' basis is the percentage of moisture in the food as it is, (partly solids + partly water).
2. Dry basis or dry matter basis (DMB) is the percentage of moisture expressed on the basis of solids only.

Example: 100 g food contains 80 g dry matter and 20 g water.

% moisture as-is = 20/100×100 = 20%
% moisture DMB = 20/80×100 = 25%

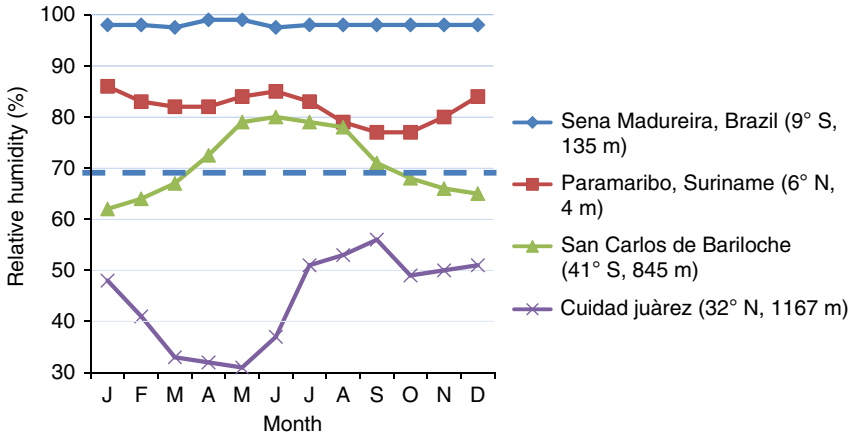

Figure 8 Mean monthly relative humidity in Sena Madureira (latitude 9° S, elevation 135 m), Paramaribo (latitude 6° N, altitude 4 m), San Carlos de Bariloche (latitude 41° S, elevation 845 m), and Cuidad Juárez (latitude 32° N, altitude 1167 m).

Both systems of expressing moisture content are widely used and both are effective. Remember to specify whether the percentage of moisture is on the as-is or DMB.

Conversion equations:

$$x\%\ \text{moisture as is} = \frac{x}{100 - x}\%\ \text{DMB}$$

$$y\%\ \text{moisture DMB} = \frac{y}{100 + y}\%\ \text{as-is}$$

Figure 8 shows the mean monthly relative humidity for four cities. As observed, cereal grains and other dry foods need to be stored at Aw < 0.70 to prevent mold growth. If the ambient relative humidity is less than 70%, the grain, if properly dried, will not absorb moisture to a level that will permit the growth of mold. The city of Cuidad Juárez in Mexico, latitude 32° N, elevation 1167 m, has a low relative humidity all year long and should experience no mold problems in stored cereal grains. San Carlos de Bariloche in Argentina (latitude 41° S, altitude 845 m) will not experience mold problems from January through March or October through December but will experience mold from April through September unless some protection against uptake of water vapor is in place. Paramaribo in SurÏnam (latitude 6° N, elevation 4 m) has a relative humidity well above 70% all year long and will need all year long protection against uptake of water vapor from the atmosphere. Sena Madureira in Brazil (latitude 9° S, altitude 135 m) has a very high relative humidity throughout the year, which means tremendous efforts are needed to prevent mold from growing in its stored dry food.

High-moisture foods

The discussion thus far has been about keeping dry foods sufficiently dry to prevent mold growth. Fruits and vegetables have a high-moisture content, typically 80–95% and a very high Aw, typically Aw > 0.98. They are vulnerable to spoilage by growth of many microorganisms. It is the skin that protects them from microbial spoilage. Therefore, maintaining intact skin to prevent invasion by microflora is necessary for preservation of horticultural crops.

Owing to their high Aw, horticultural crops easily lose water into the air causing wilting which results in a lowering of quality and loss of weight. For these products, a high humidity storage atmosphere is necessary, in contrast to cereal grains and other dry foods where low humidity atmosphere is required.

Most developing countries lie within the tropics and their high ambient temperatures make preserving the quality of stored foods considerably more difficult than in temperate climates because the naturally occurring deteriorative chemical reactions are accelerated in the tropics. In addition, the year-round high temperatures of tropical countries allow pests such as rodents and insects to feed and multiply throughout the year, whereas the cold winters of temperate zones slow down or stop reproduction and reduce the feeding activities of these pests. The low temperatures in very cold climates kill many of the pests.

Even if tropical countries had the same per capita income as the developed countries the continual high temperatures at which food must be stored pose a much more difficult set of problems than is found in temperate zones. The high relative humidity in the humid tropics compounds this problem.

Magnitude of Losses

A major question is: "How much food overall is lost in the postharvest food chain?" The honest answer to this question is that there is little reliable data. It is known that the losses are highly variable depending on the commodity, the climate, the conditions in which the food is being handled, and the length of time the food is stored. One would expect to find higher losses in perishable foods than in stable foods, and the extent of loss increases with time of storage. It is possible to find individual losses ranging from 0% to 100%, but what is of primary interest is an overall average loss figure. However, little hard data based on meticulous scientifically designed observation is available.

Harris and Lindblad (1978) developed a standard methodology to assess losses in stored cereal grains. This is the only loss assessment procedure that has a standard method. Other loss

measurements each use their own procedure and wide variations in methodology are used even for the same class of food.

A number of figures for the extent of loss quoted in scientific literature and by the communications media are unreliable because the amount of loss has been estimated and not been obtained by actual measurements. Sometimes 'worst case' figures are used to dramatize the problem. For example, care must be taken when looking at one lot of food and seeing extensive insect infestation not to assume that all food in the country is just as heavily infested. Extrapolation of loss from a limited sample to all food of a country is an unsound procedure.

Sometimes cited figures are manipulated for various reasons. There is the temptation to exaggerate loss figures when high loss figures might prompt donor aid or grants. In other cases, actual loss figures may be understated to avoid embarrassment, or for political, financial, pride, or trading reasons.

Another way loss can be exaggerated is found in the case of the subsistence farmer who harvests one crop a year and stores most of it for personal use. If the grain is properly dried most of his losses will come from insect infestation and perhaps rodents. During the first few months loss percentage is low. As storage continues, the number of insects increases exponentially and there is a very high percentage loss just before the next harvest season. However, this high loss at the end of the storage period applies only to a small fraction of the year's supply of grain. Inspection of this grain in the second month might show 2% loss which is not a great concern. By the sixth month a loss of 8% might be found which would cause some anxiety, whereas by the 10th month the loss could be 36% and cause for alarm. In this case the actual loss for the year would probably be approximately 12% of the total crop which is too high but not nearly as high as the 36% just before the next harvest. An example of time effect is given by Mushi (1978), who reported postharvest loss of maize in Tanzania at 9% after 3 months, 14% after 6 months, and 67% after 9 months storage.

Another precaution that needs to be taken in reporting losses is to ensure that the arithmetic of loss figures is correctly calculated. In quoting loss figures at various steps along the postharvest chain there is a common error of adding the percentage of loss at each stage to obtain the total loss. This leads to overall loss figures that are too large because it assumes that each loss figure is a percentage of the original weight of material. As each loss is expressed as a percentage of the amount in the previous step, the percentage is being applied to a diminishing base. An actual example of this error is shown in Table 9, which shows the apparent loss and actual loss that occurs in 1000 kg rice.

Table 9 Faulty arithmetic in assessing losses in rice

	Loss (%)	*Weight loss (kg)*	*Remainder (kg)*
Start	–	–	1000
Harvest	15	150	850
Threshing	15	128	722
Transport	10	72	650
Storage	30	195	455
Milling	20	91	364
Distribution	15	54	310
Totals	105	690	

Adding the percentage loss at each step as shown in the first column would lead to the conclusion that 105% loss occurred. Column 2 shows what the actual weight loss is at each step. The harvest loss of 15% of 1000 kg rice is 150 kg but the threshing loss of 15% is 128 kg because it represents 15% of 850 kg not 15% of 1000 kg and at the distribution end of the chain 15% loss represents only 54 kg. In this example, the overall weight loss is 690 kg or 69%, not 105%.

The 1978 US National Academy of Sciences report, 'Postharvest Food Losses in Developing Countries' summarizes the problem of assessing the magnitude of losses in these words:

> It is very difficult to estimate postharvest food losses with precision. Partly, this is due to their inherent variability. But it is also a result of many cultural and economic factors that frustrate the smooth, efficient flow of food through the postharvest system from producer to consumer….loss estimates – unlike production estimates, which are based on the measurable genetic potential of crops – are location – and season specific to a degree that makes the concept of average levels of loss almost meaningless. The low accuracy of loss survey techniques on the one hand, and the limitations of extrapolating from even a specific well characterized loss situation on the other, make reliable, economic loss estimates very difficult to obtain.

This problem is still with us in the twenty-first century.

Some Old Loss Figures

The 1978 National Academy of Sciences report gives the most extensive and best documented figures for postharvest loss up to that time. Although this is old data, it is likely that most of these loss figures are still close to the mark today. A small sample of loss data is given in Table 10 for losses of maize and Table 11 for losses in roots and tubers, fruits and vegetables.

Table 10 Reported postharvest losses of maize

Reported losses of maize in the postharvest system

Country	*Total percentage of weight loss*
Belize	20–30
Benin	8–9
Brazil	15–40
Ghana	7–14
Honduras	20–50
India	6.5–7.5
Indonesia	4
Ivory Coast	5–10
Kenya	10–23
Malawi	6–14
Mexico	10–25
Nicaragua	15–30

Newer Loss Figures

The 2011 FAO Report, 'Global Food Losses and Waste. Extent, Losses, and Prevention' is the most recent publication that gives postharvest loss figures. FAO hired the services of the Swedish Institute for Food and Biotechnology (SIK) to carry out two studies on the extent and effects, as well as causes and prevention of food losses and food waste, one for high/medium-income countries, and one for low-income countries. The two studies highlighted food losses occurring along food chains, and made assessments of the magnitude of these losses, focusing on quantitative weight losses. They compiled, analyzed, and assembled data and reports about global food loss and waste during recent years. Where information was not available, assessments and assumptions were made.

Table 11 Reported postharvest losses of roots and tubers, fruits and vegetables

Losses in roots/tubers and fruit/vegetables reported by region and country

Table 12 lists some of the data found in this report. The full report lists estimated/assumed losses for five segments of the food supply chain: (1) agricultural production, (2) postharvest handling and storage, (3) processing and packaging, (4) distribution, and (5) consumption. It should be noted that this report puts more emphasis on food waste (edible food that is discarded) than on food loss. Table 12 only lists the item 2 segment, postharvest handling, and storage.

Although many of these figures may seem low, when applied to huge quantities of food that are produced (see Table 1) the amount in tons is substantial. For example, the report 'Global Food. Waste Not, Want Not' published by the Institution of Mechanical Engineers in 2013 notes:

> Ghana, one of the more developed of the emerging West African economy, recently experienced a 50% loss rate of stored maize from a total 2008 production of one million tons. Considerably greater levels of tonnage loss exists in other larger developing nations, such as India for example, where about 2 million tons of wheat annually perish due to inadequate storage and distribution. In the neighboring Pakistan, losses amount to approximately 16% of production, or 3.2 million tons annually, where inadequate storage infrastructure leads to widespread rodent infestation problems.

Postharvest losses need not be so high. A good example of control of postharvest losses is found in the Australian wheat industry that has invested heavily in storage structures, handling practices, and insect control. Most Australian wheat is harvested during the hot dry summer months and drying to prevent fungal growth is not a problem. Analysis for the crop years 1961/62–1971/72 show that the average quantitative loss in storage is 0.249% per annum with a range of 0.138–0.675% during that decade (Bourne, 1977). This close control of all aspects of wheat handling and storage continues to this day. The 2013 report of the Institution Mechanical Engineers cited above comments, "in a developed country such as Australia, wastage of 0.75% in stored grain is at the upper end of acceptability."

Loss Reduction Activities

A wide range of activities is needed in any comprehensive program of postharvest food loss reduction activity; and because there are so many different types of foods and so many different spoilage vectors it is necessary to select an appropriate remedial activity for each specific food-spoilage combination. Table 13 lists the major causes of loss for the different food

types and the technologies needed to preserve unprocessed or minimally processed agricultural commodities.

The resources needed include:

- grain handling and drying equipment;
- storage structures of all sizes for grain and oilseeds;
- dehulling and milling equipment for grains;
- cold stores/freezer storage;
- equipment that handles horticultural crops gently;
- fumigation and other sanitation equipment;
- extraction equipment that achieves the maximum yield of sugar from cane or oil from oilseed; and
- packaging to protect the food from water vapor, oxidation, or light exposure.

All of the above items are described in other articles in this encyclopedia and require no elaboration here.

Glossary

Allocative efficiency Occurs when the quantities of variable inputs are chosen such that net value is maximized.
Allocatively efficient yield The yield that maximizes the net value of production at a particular location and point in time given existing technology and input constraints.
Maximum limiting yield The maximum yield that can be achieved at a particular location and point in time given the best existing technology for that location and time, and nonlimiting inputs other than the amount of land.
Partial factor productivity The ratio of output to the amount of a single input (e.g., land) used to produce it.
Production possibilities frontier The maximum amount of output that can be produced for each quantity of input.
Technical efficiency Occurs when the maximum amount of output is produced for a given amount of inputs.
Total factor productivity The ratio of output to an aggregation of all inputs used to produce it.

Introduction

In the past half-century, agricultural science achieved a great deal. From 3.1 billion in 1961, the world's population more than doubled to just over 7.0 billion in 2012 (an average compound rate of growth of 1.6% per year). Over the same period, total production of cereals grew faster than population (from 877 million MT in 1961 to 2546 million MT in 2012, or approximately 2.1% per year), and this increase resulted largely from unprecedented increases in crop yields (FAOSTAT, 2013; Pardey *et al.*, 2012). (Cereals include wheat, rice, maize, and other agronomic crops that are primarily used for their edible grain.) The fact that the Malthusian nightmare has not been realized in our lifetime is attributable in large part to improvements in agricultural productivity achieved through technological change enabled by investments in agricultural R&D (Alston *et al.*, 2013).

Looking forward, however, some early warning signs suggest that the period of global agricultural abundance may be coming to an end, if it has not ended already. Certainly, after decades of rapid (but slowing) decline, in real (inflation-adjusted) terms farm commodity prices have not trended down appreciably since 2000 (and have recently risen), and in recent times proportional crop yield growth rates have been slowing (Alston *et al.*, 2009). The prospect of continuing population growth and rising per capita incomes, combined with additional demand for biofuels, implies a significant increase in global demand for farm output over the decades to come. These prospects have contributed to a revival of concerns over the future capacity of the world to feed a growing population at affordable prices, giving rise to questions about the prospects for agricultural production and, in particular, crop yields. How and where will this additional output be produced with ever-tighter supplies of arable land and water, and in the face of a changing climate?

The issue of 'yield gaps' comes up in this context, in particular. (The concept of yield gaps in crops can be applied with equal force to livestock. Productivity or 'yield' gains in livestock are often delineated in terms of increases in pounds of meat produced per animal, or milk per cow, or eggs per laying hen. This is akin to tracking the amount of grain produced per plant, which is typically conceived as a harvest index (i.e., the proportion of the plant's biomass that is realized in grain rather than straw and other plant parts) rather than crop yield per se. A more natural concept of 'livestock yield' that parallels crop yields is the amount of meat, eggs, or milk produced per unit of feed or energy or some other input.) One concept of a yield gap is the difference between yields achieved by farmers in high-income countries and their counterparts in low-income countries. Can we bring up the yield of poor farmers in, perhaps, marginal areas, and by closing this yield gap reduce poverty while at the same time addressing the world food problem? (For example, a 2011 *New York Times* article by Justin Gillis defined the yield gap as "[t]he enormous gulf between the crop yields obtained by the most successful farmers and the least successful," noting that US maize yields are often five times those of small farmers in Africa. A recent *Time* magazine article (Walsh, 2012) used the term to describe "…parts of the planet where agricultural yield is lagging," with reference to "under-performing regions." This notion of yield gaps is also present in some NGO, government, and scholarly publications, such as reports from the US Department of Agriculture (e.g., Rosen and Shapouri, 2012) and the US Agency for International Development (e.g., Collier, 2012) who use a similar concept, noting the yield gap between grain yields in sub-Saharan Africa and the rest of the world.) Another concept of a yield gap is the difference between the commercial yield achieved by farmers and the experimental yield achieved by researchers. Davidson and Martin (1965), for example, report that average experiment station yields can be as much as 75% higher than average farm yields, depending on the crop and location. Can we close this gap? Should we try to do so? A third type of yield gap is the difference between experimental or commercial yields and some concept of a biological maximum potential yield. Is this gap shrinking in a way that limits our scope for increasing experimental or commercial yields in the future?

Many people are interested in closing yield gaps primarily as they relate to food security – in the sense of producing enough food at affordable prices to meet the caloric and other

 doi:10.1016/B978-0-444-52512-3.00037-1

nutritive requirements of a growing population – especially by increasing yields for subsistence farmers. But this is only one dimension of yield gaps, and closing yield gaps for subsistence farmers is only one of the many approaches for improving food security. Indeed, UN projections indicate that in the next 5–10 years the majority of the developing world's population will be urbanized, shifting attention to urban poverty and the food insecurity status of urban consumers versus subsistence producers (United Nations, 2012). Hence, rather than closing yield gaps by increasing the lowest yields, the more important concept for increasing global food security may be to increase total production by lifting the entire distribution of yields, even if that might mean making gaps larger in some cases.

In this article the issue of yield gaps is explored, primarily from an economic perspective, giving due regard to food security concerns but not at the expense of the broader considerations. Yield is an object of choice for a farmer or a researcher, determined by decisions made about technology, inputs, and management, conditioned by uncontrolled elements in the natural environment. From this perspective, yield gaps reflect differences in choices, as well as other differences in the circumstances of production that cannot be fully controlled, and attention appropriately focuses on the sources of these differences and what they imply. In the Section Economic Conception of Yields and Yield Gaps, some economic concepts are introduced. These concepts are applied to show why yield gaps might exist. The Section Measurement of Yields and Yield Gaps reviews the variety of ways in which researchers have attempted to quantify yields and yield gaps, with particular attention paid to the challenges facing such an exercise. Next, an interpretation of yield gaps in the context of global food security and agricultural science and technology policy is provided. The article ends with some concluding remarks regarding the virtue of framing the potential for global food security in terms of yield gaps.

Economic Conception of Yields and Yield Gaps

Crop yield and yield gaps are purely agronomic measures, and provide information on the outcome of a season-long production process. (There are, of course, interseasonal factors that affect yields, such as soil nutrient or water carryover, or the timing of cropping operations.) But crops involve more than agronomy: they are cultivated by farmers who make decisions about what, when, and where to plant, and the quality and quantity of inputs used to foster crop growth. Economics offers a number of conceptual and empirical tools for considering the production process in more detail, allowing one to think not only about yields and yield gaps, but also why yield gaps might exist, and whether it might be advantageous to close them. Thus, an economic perspective can add significant insight and nuance to consideration of yield and yield gaps.

Several concepts are useful for understanding yields and yield gaps from an economic perspective. First is the relationship between what is produced (i.e., the output, such as the amount of maize, wheat, or rice grain), what is used to produce it (i.e., the quantities of inputs, such as land, labor, fertilizer, water from rain or irrigation, solar radiation, pesticides, seed, and services from oxen and tractors), and how it is produced (i.e., the technology of production, which prescribes the different ways inputs can be combined to produce output). This output, input, and technology relationship characterizes the 'production possibilities.' Figure 1(a) illustrates hypothetical production possibilities for maize as more or less fertilizer is used holding other inputs constant. (Any other variable input besides fertilizer could be used to illustrate these concepts, e.g., labor, seed, irrigation water, or agricultural chemicals.) The shaded area in the figure reflects all the different combinations of maize and fertilizer that are possible given the available technology. The solid curve denoting the upper boundary of these production possibilities is known as the production possibilities frontier (PPF).

Technically, efficient production occurs where the greatest possible amount of output is produced from a given quantity of inputs or, equivalently, the least possible amount of inputs is used to produce a particular amount of output. Combinations of maize and fertilizer below the PPF (e.g., point a) are technically inefficient because more maize can be produced with the same amount of fertilizer (point b) or the same amount of maize can be produced with less fertilizer (point c). Alternatively, combinations of maize and fertilizer on the PPF

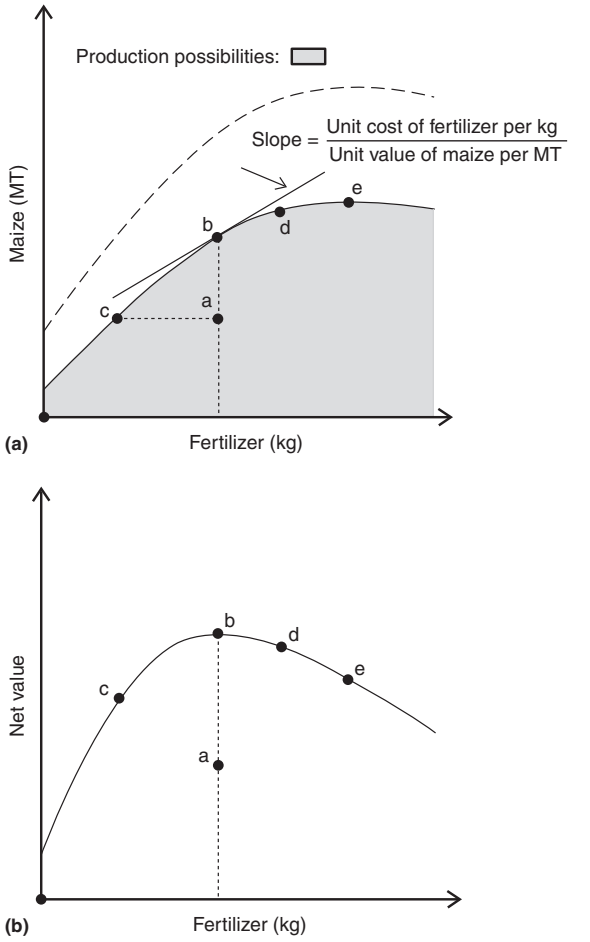

Figure 1 Hypothetical example of maize and fertilizer. (a) Production possibilities and production possibility frontiers. (b) Maximum net value of production.

(points b and c) are technically efficient because it is impossible to produce more maize with the same amount of fertilizer or the same amount of maize with less fertilizer.

Technical efficiency is one of two types of economic efficiency that are relevant in this context. If production is not technically efficient, then resources are being wasted. But as the PPF in **Figure 1(a)** illustrates, many (possibly infinite) combinations of maize and fertilizer avoid this wastefulness, and therefore technically efficient farmers or scientists could choose many different input–output combinations. For example, a scientist might set up an experiment to identify the maximum yield for a given maize variety by using an exorbitant amount of fertilizer to produce output at point e. But this ignores the second type of efficiency of interest to economists, allocative efficiency. Allocative efficiency is accomplished when inputs and outputs are combined to achieve their highest possible net value. In standard economics texts, profit is used as the relevant measure of net value, so allocative efficiency implies profit maximization. However, farmers often have objectives other than simple profit maximization. Other benefits and costs that might be viewed as important include food security for subsistence farmers, the risk of adverse health consequences from using pesticides for cash grain farmers, the risk of losses of production to pests and diseases, or business risk arising from market volatilities. Regardless of how a farmer perceives the net value of production activities, the same analytical approach can be used with appropriate adjustments to the measures used.

The solid curve in **Figure 1(b)** illustrates the maximum net value from maize production for a range of quantities of fertilizer per hectare. Points a–e in this figure correspond to points a–e in **Figure 1(a)**. The highest point on this curve is at point b, which is where production is both technically and allocatively efficient. All other input–output combinations are allocatively inefficient. Net value is lower at point a than at point b because at point b more maize is produced with the same amount of fertilizer; similarly, net value at point a is less than at point c because at point c the same amount of maize is produced with less fertilizer. Point a is technically inefficient, and technical efficiency is a necessary (but not sufficient) condition for allocative efficiency. Points c–e are technically efficient but allocatively inefficient. Points on the PPF to the left of point b (point c) are allocatively inefficient because too little fertilizer is used, whereas points on the PPF to the right of point b (points d and e) are allocatively inefficient because too much fertilizer is used given the relative cost of fertilizer and value of maize. An equivalent way to determine allocatively efficient combinations of maize and fertilizer is to find the point on the PPF where its slope equals the ratio of the unit cost (or price) of fertilizer to the unit value (or price) of maize, which is illustrated in **Figure 1(a)** at point b.

Maize cannot be produced exclusively with fertilizer. Maize seed, a place to plant the seed and other inputs are also required. The relationship illustrated in **Figure 1(a)** embodies an assumption that quantities of all other inputs being used to produce maize do not change as the amount of fertilizer changes. This assumption explains why the PPF in **Figure 1(a)** becomes flatter as the amount of fertilizer increases and eventually begins to decline. Holding the amount of seed and land constant, plant growth can be severely nutrient limited without any fertilizer, so little will be produced. As the amount of fertilizer increases, crop growth becomes more vigorous and more is produced. (This is a hypothetical example. Of course, application of fertilizer does not always increase crop yields. For example, Sileshi *et al.* (2010) found that the addition of enough fertilizer could actually reduce maize yields in some parts of sub-Saharan Africa in some years.) Eventually, with enough fertilizer, growth will no longer be nutrient limited and the amount produced will be as great as possible given other available inputs. Continuing to increase fertilizer beyond this point can become detrimental, leading to a decrease in output. This flattening of the PPF and its eventual decline as the variable input increases is known as diminishing marginal returns – each additional kilogram of fertilizer increases the amount of maize produced by less than what the previous kilogram did. If the amount of seed or land used to produce maize is doubled, the relationship between the amount of maize produced and fertilizer changes, which is illustrated in **Figure 1(a)** by the higher dashed curve. Similar shifts in the PPF could result from changes in quantities of other inputs, such as labor, or the addition of irrigation or some other change in technology, such as switching from landrace to improved seed varieties. Upward shifts in the PPF could also result from changing where maize is produced to a place with more productive soils or more favorable weather.

Considering these additional inputs, the farmer is free to vary more than one, and potentially all of them. Those inputs that the farmer can freely vary are referred to as variable inputs; those that the farmer cannot freely vary are referred to as fixed inputs. In the ultimate long run, all inputs are variable, but over shorter planning horizons, some inputs are better treated as fixed. Thus, within a season, hired labor, irrigation water, fertilizer, and pesticides are typically regarded as variable inputs, whereas capital inputs (such as the available machinery), land, and its attributes (terrain, rainfall, and solar radiation) are regarded as fixed. In this context, allocative efficiency more generally refers to farmers choosing all variable input quantities, not just the quantity of fertilizer, such that net value is as high as possible. Economists use the net value function to represent the highest net value that could be earned from freely choosing the quantities of all variable inputs. These inputs are chosen in response to the unit cost of inputs and unit value of outputs, and the quantities of fixed inputs. (These ideas apply both to commercial or subsistence farmers. Even if farmers do not directly participate in output (or input) markets, they do make optimizing decisions based on the opportunity cost (or shadow prices) of inputs and outputs. As Schultz (1979) observed in his Nobel Prize lecture: "Farmers the world over, in dealing with costs, returns and risks, are calculating economic agents. Within their small, individual, allocative domain they are fine-tuning entrepreneurs, tuning so subtly that many experts fail to recognize how efficient they are.")

The net value function shows how the maximum net value varies as farmers choose allocatively efficient combinations of variable inputs and output. As the technology of production is embodied in the net value function, it can be used to derive the allocatively efficient quantity of output given the unit costs of variable inputs, the unit value of output, and the quantities of any fixed inputs. Likewise, the net value function can be

used to derive the demand for land (when it is a variable input) as a function of the same variables. Thus, both the allocatively efficient quantities of output produced and land used can be expressed as functions of the unit cost of inputs and the unit value of output, technology and the quantities of fixed inputs, and therefore the allocatively efficient yield can also be derived as the ratio of these quantities. (In practice, when some production decisions are made farmers do not know the ultimate realization of some variables, such as rainfall, solar radiation, and output prices. For example, the farmer typically does not know the final output price when deciding on the amount of fertilizer to apply or the area to plant. Thus, decisions are based on expectations of likely realizations and distribution of these uncertain variables.)

The important point is that even in the more general multi-input case, the allocatively efficient yield depends on the unit cost of inputs and the unit value of output, the quantities of fixed inputs, technology, and the quantities of other factors over which producers have no choice in a given cropping season, and all these factors vary across farms and over time. As a result, even if farmers are making technically efficient, or even allocatively efficient use of land and other inputs, 'yield gaps' could be observed across farms insofar as input unit costs, output unit values, or the quantities of other fixed inputs also vary, dictating different choices. Enduring 'gaps' in yields between any two farmers, such as one in the US mid-West and one in Malawi, may reflect persistent differences in their constraints and opportunities as indicated by differences in their economic or agroecological circumstances, reflected, for example, in input unit costs, output unit value, pest pressure, access to public infrastructure, or weather.

Yield as a Productivity Measure

Yield, defined as the output of a crop (e.g., amount of grain or other crop product) per unit of land used to produce it (e.g., metric tons of maize per hectare), is one of the most common measures of crop productivity. (In **Figure 1(a)** there is a one-to-one correspondence between the quantity of maize output (as plotted) and maize yields, that is output per unit area, because in this example all other inputs, including land area, are fixed – only the rate of fertilizer used on that given area varies. Similarly, and for the same reason, there is a one-to-one correspondence between the amount of fertilizer used (as plotted) and the rate of fertilizer application, that is the amount of fertilizer used per unit area. Yield is considered a 'partial productivity' measure because land is not the only input used in production. Partial productivity could also be measured in terms of crop output per unit of any of the other inputs used to produce it, such as fertilizer, labor, seed, or irrigation. Different partial productivity measures can lead to different conclusions. For example, averaging 2010 production at the continental scale, US farmers produced approximately 9.6 MT ha^{-1} of maize using 152 kg ha^{-1} of nitrogen fertilizer and sub-Saharan African (SSA) farmers produced 1.9 MT ha^{-1} of maize using approximately 9.7 kg ha^{-1} of nitrogen such that 61 kg of maize per kg of nitrogen was produced in the United States whereas 194 kg of maize per kg of nitrogen was produced in sub-Saharan Africa. (United States values were derived using area and output data from FAOSTAT (2013) along with USDA fertilizer use data (USDA, ERS 2011). SSA values were estimated using area and output data from FAOSTAT (2013), an estimate of average SSA nutrient application on maize (Smale *et al.*, 2011), and applying typical NPK shares from Alexandratos and Bruinsma (2012).) By these measures, US farmers appear more productive than SSA farmers in terms of land, but not as productive in terms of nitrogen, which highlights the perils of naïve interpretation of partial productivity measures like yield; namely, productivity with respect to any single input (e.g., land or fertilizer) could easily lead to inaccurate conclusions about the overall productivity of a system.

Furthermore, a difference in crop yield between countries or regions is not, in itself, sufficient for drawing definitive conclusions about productivity. The 2011 average Australian wheat yield (2.0 MT ha^{-1}) was less than one-third of the national average wheat yield of France (6.5 MT ha^{-1}), but this difference mainly reflected relatively low land quality and rainfall in the growing environments of Australia rather than any technical or allocative inefficiency in Australian wheat production. (This yield difference might also reflect the influence of differences in incentives for producers provided by European Union subsidies and other policy differences. The 2011 yields are from FAOSTAT (2013).) Even within a country, crop yields differ substantially over space: The 2007 US Census of Agriculture reports that nonirrigated maize yields were 2.5 times higher in Illinois than in Alabama. Although these yield differences can reflect regional differences in the environment, they can also reflect differences in socioeconomic circumstances such as opportunities for off-farm employment of farm family members and other dimensions of input costs, educational attainment, family structure, cultural norms, social and public infrastructure and related services, the nature of markets for farm outputs, and other determinants of the unit value of farm output. Such differences exist in market-driven agricultural systems as well as in subsistence agricultural systems.

Ideally, analyses of production, yields, or yield gaps would consider the production from the entire crop rotation of an enterprise or region and not focus on individual crops (Siebert *et al.*, 2010). Additionally, taking account of inputs other than land would allow for a more complete accounting of productivity and the sources of output growth. One way to take account of crop rotations, cropping intensity and multiple inputs is to apply total factor productivity (TFP) metrics to measure the relationship between all outputs and the amount and quality of all inputs used in production, rather than measure yield, which is a partial factor productivity (PFP) metric considering only the ratio of output to the amount of a single input (e.g., land) used to produce it. (Multifactor productivity (MFP) metrics include only some inputs and outputs, whereas TFP metrics ostensibly include all inputs and outputs. Some argue that TFP is a misnomer insofar as it is impossible to capture and properly measure all of the inputs to production (Alston *et al.*, 2010).) But even an increase in TFP does not guarantee that either yield or output has increased. Although TFP is closely related to the notions of efficiency discussed in this article, changes in TFP for a region over time can also reflect changes in the economic scale of

farm operations or changes in technology. Nonetheless, changes in TFP give a more complete accounting of the sources of growth than do changes in yields or yield gaps.

Total output equals total land under production multiplied by the corresponding yield such that increases in production can be thought of in terms of extensification, increasing the amount of land under production, and intensification, increasing the yield per unit of land. (Focusing on output per unit of land puts undue emphasis on land as a limiting factor in economic growth. For example, Schultz (1951) pointed to the declining economic importance of agricultural land; not only because the agricultural share of economic output has declined, but also because "… the value added by land … declined relative to all inputs used in farming" (p. 735). Although there are prospects for extensification (Pardey *et al.*, 2014), scientists and policymakers often emphasize intensification options as a means to increase crop production because, among other reasons, it is supposed that increasing the land area under production might exact a higher environmental cost than does increasing yields (Garnett *et al.*, 2013). Indeed, approximately 76% of the increase in aggregate crop production worldwide from 1980 to 2010 resulted from intensification, with only 24% attributable to extensification. (This figure is an approximation and is intended for illustrative purposes. The measure of total output is derived by aggregating crops by weight based on data from FAOSTAT (2013).) Thus, it seems, both the historical importance of and policy preference for intensification have led many researchers to focus on the limits to intensification in terms of yield gaps and the potential for closing these gaps as a means for feeding an increasing world population.

Yields, Yield Limits, and Yield Gaps

Because yield measures output per unit of land, it embodies the assumption that production is land constrained, making it subject to diminishing marginal returns and some absolute limit. The gap between this limiting yield and the observed yield bounds how much intensification can potentially increase production. Many conceptualizations and strategies for quantifying the limiting yield have emerged in the yield gap literature with a notable lack of standardization. The quantification of observed yields has also varied. Despite this lack of consistency, key ideas emerging from the literature can be parsimoniously framed from an economic perspective using four quantities:

- Actual yield (Y^{A}) – the measured yield at a particular location and point in time.
- Allocatively efficient yield (Y^{AE}) – the yield that maximizes the net value at a particular location and point in time given existing technology and input constraints.
- Limiting yield (Y^{L}) – the maximum yield that can be achieved at a particular location and point in time given existing technology and input constraints.
- Maximum limiting yield (Y^{ML}) – the maximum yield that can be achieved at a particular location and point in time given the best existing technology for that location and time, and nonlimiting inputs other than the amount of land.

The terminology used here intentionally differs from that used in previous studies to reduce the confusion that would come from having multiple definitions for the same terms. The terms are also defined relative to the economic concepts previously developed and illustrated in Figure 1 to further promote clarity. These four quantities make it possible to carefully define the yield gap as well as to identify distinct reasons for its existence.

The maximum limiting yield is the most that can be produced assuming land is the only constraining factor, given existing technology. This is illustrated in Figure 2 as Y^{ML} where the dashed curve represents the PPF for fertilizer and maize yield assuming the best available technology of the time is used, and inputs other than fertilizer and land are not limiting yields. The maximum limiting yield occurs where this dashed PPF reaches a maximum because fertilizer is also no longer limiting. It is important to remember that the maximum limiting yield is both location- and time-specific. As new technologies are developed over time the maximum limiting yield will also change, resulting in shifts in the dashed PPF.

The limiting yield, illustrated in Figure 2 as Y^{L}, falls short of this maximum limiting yield because of constraints on technology or inputs other than land. For example, farmers may not have access to pesticides, certain improved seed, or other inputs or technologies, owing to a range of socioeconomic and institutional factors. Therefore, the limiting yield occurs at the maximum of the PPF that reflects these technology and other input constraints as illustrated by the solid curve. An upward shift in this solid PPF can be accomplished by alleviating various constraints, though, by definition, the solid PPF could never exceed the dashed PPF. The difference between the maximum limiting yield and limiting yield results in one type of yield gap: $Y^{ML} - Y^{L}$.

The actual yield, illustrated by Y^{A} in Figure 2, typically falls short of the limiting yield. This can occur because input use is technically efficient, but not high enough to achieve the

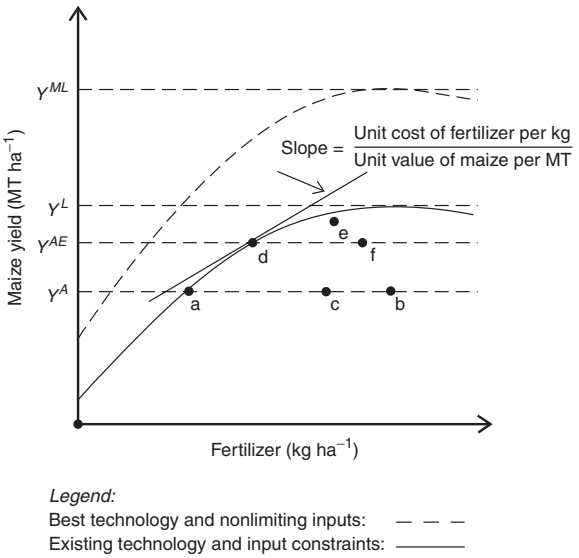

Figure 2 Hypothetical example of maximum limiting Y^{ML}, limiting, allocatively efficient, and actual yields when fertilizer is used to produce maize.

limiting yield (point a). It can also occur even if enough of the input is used to reach the limiting yield, but input use is technically inefficient (point b), or because not enough of the input is used to reach the limiting yield and what is used is technically inefficient (point c). The difference between the limiting yield and actual yield results in a yield gap: $Y^L - Y^A$.

The gap between limiting and actual yields can be decomposed into the gap between limiting and allocatively efficient yields and the gap between allocatively efficient and actual yields: $Y^L - Y^A = (Y^L - Y^{AE}) + (Y^{AE} - Y^A)$. The allocatively efficient yield occurs where the slope of the PPF with existing technology and input constraints equals the ratio of the unit cost of fertilizer to the unit value of maize, represented by point d in Figure 2. A gap between limiting and allocatively efficient yields is inevitable whenever inputs are costly to use or farmers have a limited ability to secure the input (e.g., because of poorly functioning credit markets or lack of public infrastructure). For example, if the unit cost of fertilizer in Figure 2 were zero, then the fertilizer-to-maize unit cost-to-value ratio would also be zero, such that the limiting and allocatively efficient yields would coincide (at Y^L). A gap between allocatively efficient and actual yields is not inevitable. Indeed, some economists argue it is nonexistent because the actual yield ultimately reflects the choices of farmers based on their own objectives and perceived values and costs, so it must be allocatively efficient. (That is, Y^A, corresponds to the output of maize that maximizes the value of production to farmers (point b in Figure 1(b)). The core of the argument is that any difference between Y^A and Y^{AE} results because the analysis has failed to properly incorporate the constraints faced by the farmer, the farmer's technology or the farmer's values.) Others argue that a gap between allocatively efficient and actual yields can and does exist for many farmers. Typically, this gap is presumed to be positive as is the case with the difference in yield between points d and a, b, or c illustrated in Figure 2, but this need not be the case if, for example, the observed yield actually corresponded to point e. Moreover, such gaps arise from either allocative inefficiencies (e.g., the difference in yields between points d and a) or technical inefficiencies (e.g., the difference in yields between points d and c or b).

Production at point f in Figure 2 further illustrates the drawbacks of using partial productivity measures like yield and yield gaps as a focus of policy discussions on food security. The yield corresponding to point f is identical to the allocatively efficient yield corresponding to point d. However, production at point f is technically and allocatively inefficient because too much fertilizer is used. Therefore, it is possible for production to be inefficient even if there were no gap between the allocatively efficient and actual yields.

The relationships illustrated in Figure 2 show how the overall gap between the maximum limiting and actual yields can be decomposed into the gaps between maximum limiting and limiting yields, limiting and allocatively efficient yields, and allocatively efficient and actual yields: $Y^{ML} - Y^A = (Y^{ML} - Y^L) + (Y^L - Y^{AE}) + (Y^{AE} - Y^A)$. How each of these gaps can be closed and whether it should be closed requires very different policy considerations.

Closing the gap between maximum limiting yield and limiting yield requires addressing the factors that are hindering access to better technology and inputs. In sub-Saharan Africa, for example, in many places the provision and adoption of improved technologies that would allow higher yields and lower costs of production for maize have been hampered by a lack of public infrastructure or by incomplete or nonexistent markets for credit, fertilizer, or other inputs, or by poor intellectual property rights applicable to agricultural technologies. In contrast, in the United States and other high-income countries, the comparable infrastructure, markets, and institutions function comparatively well and market-based incentives are much more effective (although that has not always been so, most notably if US crop yield performance is considered in a long-run historical context). If yields in sub-Saharan Africa could be lifted toward their US counterparts by improving markets for inputs or building better infrastructure, farmer (and consumer) welfare would be improved, but other ways of improving welfare may be more economical.

The gap between limiting and allocatively efficient yields can be closed by policies that reduce the unit cost of inputs or increase the unit value of output to farmers – whether these are measured using market prices or implicitly in terms of the opportunity cost for farmers, such as the value of their time or the value of at-home consumption of their products. But, if the market prices of outputs and inputs accurately capture their social value and costs, policies that interfere in the market may hurt other groups more than they benefit farmers. Thus, such policies might only be warranted if they are aimed at correcting some market distortion. (For example, consider the environmental costs (damages) imposed on society through the use of certain chemicals in agricultural production. If farmers are not liable for such damages, they may use more of the chemicals than they would if they were liable for environmental damages. A policy that lowers the price of such inputs might increase these external costs.)

Closing the gap between allocatively efficient and actual yields, if one exists, requires policies that promote the technical and allocative efficiency of farmers, so their input and output choices are less wasteful and capture as much of the value of production as possible, which could be of benefit to farmers and society as a whole. Such policies might include funding of educational extension programs and dissemination of market information to aid farmers in selecting efficient input mixes, or reducing distortions in market prices and the incentives they convey to farmers, such as, for example, in high-income countries that encourage the overuse of fertilizer and other agricultural chemicals by subsidizing output and failing to tax agricultural pollution.

Measurement of Yields and Yield Gaps

The quantification of yield gaps requires the measurement or estimation of a limiting yield as a counterfactual point of comparison for the actual yield. (Crop yields are usually defined in terms of the primary product of the crop. So, for example, maize output is typically measured in tons of grain, not in tons of total biomass produced. Traxler and Byerlee (1993) analyzed the uptake of semidwarf wheat varieties in the context of the demand for the joint (straw and grain) products from growing this crop.) The theoretical maximum yield based on crop physiology independent of realized

genetic improvements attracted interest in the 1960s and 1970s in relation to maximum limiting yields, especially from Dutch researchers, such as de Wit (1967) and Linneman *et al.* (1979) (as cited in Plucknett, 1995). However, although the theoretical maximum yield is referenced in the yield gap literature, it has not been widely adopted to either conceptualize or quantify the maximum limiting yield. Instead, the notion of potential yield, defined by Evans (1993, p. 26) as "the yield of a cultivar when grown in environments to which it is adapted, with nutrients and water nonlimiting, and with pests, diseases, weeds, lodging and other stresses effectively controlled," has been used more consistently to conceptualize the notion of a maximum limiting yield. A feature of this definition that distinguishes it from the theoretically maximum yield of a crop species is that it is defined relative to the best adapted cultivar for a particular environment. As land is heterogeneous across space and time in terms of soil and weather, and cultivars have continuously improved and become more highly adapted to specific environments, potential yield is a spatially and temporally varying concept. Although Evans-type definitions are most common, it is not clear that that they are actually quantifiable; as Cassman (1999) notes, such potential could not be measured in the field because it is impossible to completely mute all crop stress.

Potential yield as defined by Evans is location- and time-specific, which makes it most appropriate for quantifying yield gaps at the scale of a farm (or even farm field) in a particular year. Other notions of limiting yield for comparison to actual yield have cropped up in studies that attempt to quantify yield gaps at a landscape scale. These landscape studies rely on empirically based definitions of limiting yields, though they still maintain some notion of time- and location-specificity through the use of reference years and climate homologs. Although the empirical nature of these landscape definitions makes them easier to quantify, they are conceptually different from definitions like that of Evans. To better understand some of the key differences between perspectives on yield gaps at the farm level and at broader spatial scales, it is useful to briefly review the different strategies that have been employed in these two strands of literature. (Another way yield gaps have been measured is as the difference in yields between countries or regions (Trueblood and Arnade, 2001; Gillis, 2011; Walsh, 2012; Rosen and Shapouri, 2012; Collier, 2012) or production systems (De Ponti *et al.*, 2012; Yang *et al.*, 2008; Paez, 1973). These strategies for yield gap measurement are distinct from the more common field/farm and landscape scale studies because they ignore the location specificity of the production environment.)

Farm Yield Gap Measurement

The early literature on yield gaps relied heavily on measures of yields from intensively managed experiments on farmers' fields or experiment stations to quantify the maximum limiting yield, though researchers recognized that the limiting yields achievable by farmers in practice would likely differ from these experimental yields because of differences in environmental, socioeconomic, or other constraints faced by farmers, but not researchers (Davidson *et al.*, 1967; Gomez, 1977). (It is common in the yield gap literature to view economics as a 'constraint.' This reveals an agronomic point of view in which the counterfactual ideal yield is the limiting yield, even though the limiting yield is unlikely to be economic.) This distinction between the yield achievable in experiments and the yield achievable on the farm led Gomez (1977) and subsequent researchers to define different types of yield gaps; for example, Yield Gap I equal to the difference between the achievable and experimental yields and Yield Gap II equal to the difference between the achievable and actual farm yields. The International Rice Agroeconomic Network, an International Rice Research Institute (IRRI)-led consortium, measured achievable yields by conducting on-farm experiments to reduce the gap associated with potential environmental differences between farms and experiment stations, and thus the achievable yield roughly corresponds to the farm-level limiting yield defined in this article. The early multidisciplinary work at IRRI showed exceptional bio-economic clarity in its framing of yield gaps. This work includes Herdt and Wickham (1975), IRRI (1977 and 1979), De Datta *et al.* (1978), Herdt and Mandac (1981) and others. Our economic conceptualization of yield gaps draws from and repositions these foundational works.

The lines drawn between limiting and allocatively efficient yields and between allocatively efficient and actual yields are motivated by distinctions like those between Yield Gaps I and II proposed by Gomez (1977). However, these early yield gap distinctions did not always clearly delineate between gaps resulting from technical inefficiencies, rational economic behavior, and more fundamental social, cultural, institutional, or economic constraints, making it difficult to understand the practical and policy implications of alternative gaps.

Herdt (1988), as cited in Pingali and Heisey (1999), found that experiment station yields decreased markedly when the objective of the experiment was changed from yield maximization to profit maximization, which led Pingali and Heisey (1999) to argue that differences between farm yields and experiment station yields designed to maximize profits provide a measure of the "exploitable yield potential" (p. 21). This notion of exploitable yield potential is analogous to allocatively efficient yields, assuming farmers are primarily interested in profit maximization. Alternatively, if farmers are also concerned with risk avoidance as argued by Herdt and Wickham (1975), the analogy between exploitable yield potential and allocatively efficient yield begins to wither.

Duvick and Cassman (1999) assert that contest winning yields provide another and better approximation of farm-level limiting yields, whereas Specht *et al.* (1999) warned that contest winning yields "… arise from favorable confluences of genotype, management, soil type, rainfall, weather, etc." (p. 1568) that are unlikely to be scalable across large production areas. Crop growth models offer another way to quantify the maximum limiting yield (e.g., Becker *et al.*, 2003) that has not been as widely adopted because critics have worried about how well such yields capture what farmers can achieve (Lobell *et al.*, 2009), the need to frequently update the models to reliably capture a changing genetic landscape (Fischer and Edmeades, 2010), and the potential for errors and uncertainties in the modeled yields to exceed the actual yield gap (Neumann *et al.*, 2010).

Yield Gap Measurement at Landscape Scales

More recently, the literature has turned to assessments of yield gaps at broader spatial scales than the farm level, including regional and global assessments; these 'landscape scale' assessments generally are undertaken with a view to better targeting productivity-enhancing interventions and investments. Although the details of these assessments vary across studies, the general approach is to represent actual yields using global estimates such as those found in Monfreda *et al.* (2008). In these datasets, the world is partitioned using a grid of pixels (i.e., a raster), with estimates of the actual average yield for each pixel in which the crop is likely to be grown. These global methods also differ in how the limiting yield is estimated for comparison to the actual yield. Using raster data on weather (moisture and temperature), Licker *et al.* (2010) divided the world into 100 climate zones such that each zone ostensibly has a similar temperature and moisture profile (measured using growing degree days and a soil moisture index). The authors then constructed a cumulative distribution of yields across the constituent pixels in each zone and took the 90th percentile (e.g., the minimum yield of the top ten percent of yielding pixels in each zone) as the limiting yield of the zone given its temperature and moisture profile. (The choice of the 90th percentile by Licker *et al.* (2010) was apparently somewhat arbitrary, although the authors expressed concern that higher values in the yield dataset might be "erroneous or overestimated" (p. 774). Others have used the 95th percentile and one could argue for use of the maximum yield for a climate zone as the limiting yield for that zone.) The yield gap of each pixel was then calculated as the difference between the limiting yield in the corresponding zone and the estimated actual yield in the pixel. Foley *et al.* (2011) and Mueller *et al.* (2012) similarly define the limiting yield for each pixel as the 95th percentile of the yield distribution for pixels with similar rainfall and temperature regimes. It is worth emphasizing that defining limiting yields as an arbitrary percentile of a yield distribution is conceptually different from defining limiting yields based on simulated or experimental yields. As the yields in these distributions are actually observed, they will tend to generate conservatively small estimates of limiting yields. (This is especially true when the yield distribution is made up of pixel-level yields because pixel yields are already a spatial average yield (and in some cases, a temporal average as well).)

The coarse measures of temperature and rainfall used in climate homolog methods do not fully describe the growing environment. Indeed, intraseasonal patterns of rainfall and temperature, and the occurrence of weather events relative to the lifecycle of the crop are extremely important in explaining yields (Beddow *et al.*, 2012). As the methods abstract from the intraseasonal extremes of temperature and drought that generate crop stress, they do not generate estimates of potential yield that are in the spirit of Evans (1993). Further, the binning procedures – whereby pixels are grouped into homologs based entirely on some selected agroecological attributes – do not embed spatially sensitive information on input costs or output values and other socioeconomic factors. Thus, both the limiting and allocatively efficient yields may be different for each pixel even if pixels are in the same climate homologs.

This strand of literature does not tend to employ concepts analogous to the maximum limiting yield, though in some sense the maximum yield observed within the distribution of yields in a climate homolog might be interpreted as such. The distinction of allocatively efficient yields is also not typically quantified. Neumann *et al.* (2010), who estimate a stochastic production frontier based on global pixelated yield data, provide an exception to some extent. This stochastic production frontier method incorporates monthly temperature deviations, monthly precipitation, solar radiation, and a measure of soil fertility as inputs in an attempt to quantify the source of technical inefficiencies. Therefore, the method does not explicitly quantify allocatively efficient yields, but it does measure part of the gap between allocatively efficient and actual yields. However, because the set of inputs employed by the authors is limited, what appear to be technical inefficiencies may actually reflect differences in unmeasured inputs related to farmers' management choices or other environmental factors, which could bias the results.

Practical Challenges to Measuring Yield

To quantify yield gaps well requires access to accurate and meaningfully comparable measures of actual yields; whether they are used directly in forming estimates of gaps in yields or indirectly as a basis for calibrating modeled crop yields. However, estimating crop yields that are statistically accurate (or 'true' in ISO parlance) and precise is difficult. Survey-based methods are typically used to estimate average yields (which are usually derived from estimates of planted or harvested area and corresponding estimates of grain production) at county, state, or national scales, but the nature, accuracy, and comparability of these surveys vary markedly over time, across countries, and among crops.

For example, in the United States, objective measures of average maize yields at county scales and above begin by establishing an 'area frame,' from which a probability-proportional-to-size sampling of farm fields is taken. Two parallel, 15 ft. sections of rows within each sampled maize field are then surveyed by trained enumerators who collect the information required to estimate the number of ears per acre and the (standardized moisture content) grain weight per ear that in turn are used to estimate total crop production and average yields (USDA-NASS, 2012). Remotely sensed data coupled with an array of modeling methods are increasingly being used in conjunction with ground-truthed data to generate (georeferenced) crop area, yield, and production landscapes (Bailey and Boryan, 2010).

In other, often developing-country contexts, crop cut or farmer estimates have been the primary means by which crop production, area, and yields are estimated. ('Crop cut' refers to a set of methods for estimating crop quality and yield by harvesting or sampling small portions of fields. Procedures differ, but in general the goal is to scale up the yield of the sampled area to estimate a yield for the entire field or farm.) These estimates are prone to substantial sampling biases and measurement error. This is especially so in the complex

cropping systems characterizing many smallholder operations in low-income countries. The inability to assure a spatially representative sampling of farms, perhaps stratified by size, production systems (e.g., irrigated vs. rainfed), and other relevant attributes, is just the first of many sources of measurement error. Smallholder farms are often subdivided into plots, wherein crops are grown in pure stands as well as multi- or intercropped systems involving two or more crops planted on the same plot in a season, and in many instances involving at least two and in places three cropping seasons per year (Dalrymple, 1971; Poate and Casley, 1985; Fermont and Benson, 2011). In these circumstances, subplot crop cutting methods are often used to estimate yields (and production), introducing a host of potential estimation errors. For example, Poate and Casley (1985) suggest crop cutting methods tend to overestimate yield via a combination of 'edge effects' (plants that lie fractionally outside the subplot are included in the count), 'border bias' (location methods may over- or underestimate the boundaries of a plot), and nonrandom location of the subplot (enumerators tend to avoid bare or sparsely populated parts of the plot) (Also see FAO, (1982) and Murphy *et al.*, (1991)). The timing of the crop cuts matters too; especially for cropping systems in which individual plants within a particular crop stand, or different crops within each (sub-)plot, mature at different times.

Crop cuts generate estimates of the quantity of production, which carry with them problems of standardization by form – fresh or processed, shelled or unshelled, with or without stalk, polished or unpolished, in the cob or seeds only, or some other form – standardization by moisture content, and standardization by type (e.g., Durum vs. winter or spring wheat). To report yields (or to upscale crop-cut or farmer estimates of plot-level yields to estimate total production) at larger spatial scales also requires commensurate measures of planted or harvested area. A host of conventional area measurement techniques are used (e.g., Poate and Casley, 1985; Poate, 1988), increasingly complemented by handheld PDA devices (Keita *et al.*, 2010). None of these area estimation approaches is without error. Newer GPS aided devices are imprecise on very small plots (say less than 0.01 acres), but are more accurate on larger plot sizes, where they reveal a seemingly systematic tendency for farmers to overestimate the size of small plots (by upwards of 90%) and underestimate the size of large plots (by upwards of 59%) (Carletto *et al.*, 2013).

The comparability of yields taken at a point (say on-station yields, or on-farm experimental yields taken from one or a few farms) versus the estimated average yield in the surrounding or adjacent region is also problematic. Crop yields are typically much more variable at the field level than at the regional level (e.g., Lobell *et al.*, 2007) and farm yields are often not symmetrically distributed even within a field (e.g., Hurley *et al.*, 2004), so that a regional average yield may not represent the yield of a typical farm, and thus the calculated yield gap may not be representative of the region being studied. That point estimates of limiting yield (e.g., from an experiment station or highest yielding farm) are essentially incomparable with regional or national average yields was noted by Barker (1979), who deemed such comparisons "… newsworthy (but scientifically worthless)…" (p. 10).

Interpretation of Yield Gaps

Meaningfully measuring the magnitude of a yield gap is one challenge. Another challenge is drawing actionable insights with meaningful scientific, farm management, economic, or policy implications.

Are Yields Gaps Good, Bad, or Irrelevant?

Two somewhat contradictory views of the importance of yield gaps to food security might be taken. One view is that yield gaps are necessary for improvements in farm yield, and as the yield gap decreases, because the actual yield is approaching the limiting yield, it is increasingly difficult for farmers to improve yields such that yield growth rates slow (Grassini *et al.*, 2011; Cassman, 1999; Pingali and Heisey, 1999; Cassman *et al.*, 2003). The natural conclusion is that small yield gaps are a bad omen for future food prospects, and that a robust way to address food security concerns is to increase yield gaps by raising the limiting yield through breeding programs for example. However, the evidence to support a relationship between smaller yield gaps and slower yield growth is not entirely clear (Evans and Fischer, 1999).

A second view is that yield gaps are indicative of potential problems that could be addressed by changing farmer behavior, natural environments or markets. From this viewpoint, 'closing' the yield gap is a way forward to sustainably increase agricultural output (Mueller *et al.*, 2012; Foley *et al.*, 2011). In this context, yield gaps show where output gains might be realized by tackling the biotic, abiotic, and socioeconomic constraints to yields. For example, Herdt and Wickham (1975) first discuss constraints that lead to the gap and then suggest research and investment as a way to relax these constraints. Still, whereas yield gaps might show where improvement is technologically possible, this does not necessarily imply improvement is economically or socially feasible or desirable.

Closing yield gaps is not a necessary condition for increasing output via agricultural intensification. A historical example from the United States serves to illustrate. The improvement in maize output over the past century in the United States is an example of a successful intensification effort, especially from the perspective of increasing global food and feed supplies. Consider the period 1889 through 1954. In the earlier years conditions in US agriculture were comparable to current conditions in many low-income regions, with smaller farms, poor rural infrastructure, comparatively limited use of off-farm inputs, and so on (e.g., Gardner, 2002). But the average maize yield in the United States grew significantly. It increased from just over 1.8 MT ha^{-1} in 1899 to approximately 2.5 MT ha^{-1} in 1954. Over the entire period 1889–2007, the average US maize yield increased to 9.3 MT ha^{-1} such that output sextupled even though the amount of US harvested land devoted to maize increased by only approximately 20%. Using county-level annual yields, the authors approximated the methods of the global yield gap studies (e.g., Foley *et al.*, 2011 and Mueller *et al.*, 2012) and measured yield gaps as the difference between the yield for a particular county in a particular year and the 95th percentile of the yield distribution for that year. (These yield gaps (G) were calculated

for each county, i, and year, t, as $G_{i,t} = \max(Y_t^L - Y_{i,t}^A, 0)$, where Y_t^L is the 95th percentile of the county yield distribution for time t and $Y_{i,t}^L$ is the reported ('actual') yield for the corresponding county and year. The area-weighted mean gap, $\sum_i G_{i,t} a_{i,t} / \sum_i a_{i,t}$ was used as the national yield gap, which was expressed as a percentage of Y_t^L. It is worth noting that slight variations in the way in which the yield gap is calculated or presented can change the results. One could argue effectively for use of unweighted, area-weighted or output-weighted yield gaps, gaps as a percentage of farm yield, calculating the limiting yield using various percentiles of the yield distribution, and so on. In the present data, the absolute yield gap increased between 1889 and 2007, whereas the yield gap expressed as a percentage of Y_t^L decreased (from ~31% to 19%). The gap decreased substantially more (from 80% to 29%) when expressed as a percentage of farm yields.) Although the national yield improved markedly during both periods, this measure of yield gaps increased between 1889 and 1954, and decreased between 1954 and 2007.

More particularly, increases in regional yields do not necessarily imply decreases in the region's yield gap. Figure 3 shows the spatial distribution of US maize yields for 1889, 1954, and 2007, along with the cutoff for the limiting yield (estimated as the 95th percentile of the county yield distribution). The average yield increased between 1889 and 1954, but the larger yield increases tended to be seen at the high end of the distribution, thus increasing the national yield gap. By 2007, the distribution had become much more symmetric, decreasing the yield gap. Thus, changes in the distribution of yields can affect yield gaps, even causing the yield gap to increase while average yields are improving. Indeed, a region's yield might be distributed such that the yield gap could change between two years even if the same amount of output were produced in both years using the same amount of land (and thus the regional yield would not change). (Many distributions exhibit this phenomenon. For example, consider a simple case in which, in a given year, half of a country's hectares had a yield of 7 MT ha^{-1} and the other half yielded 8 MT ha^{-1}. The national yield in that year was 7.5 MT ha^{-1}. Suppose that the country's yield distribution changed the following year, such that half of the hectares yielded 5 MT ha^{-1} and the other half yielded 10 MT ha^{-1}. Again, the national average yield was 7.5 MT ha^{-1}. Using the 95th percentile of the yield distribution as the limiting yield, the first time period had a yield gap of 6.25%, whereas the second year had a yield gap of 25% even though the same amount of output was produced on the same amount of land.)

Lack of Standardization and Potential for Manipulation

Yield gaps often entail the comparison of some observed yield with a counterfactual limiting yield. The preceding discussion noted several ways in which the limiting yield might be estimated. Because the measure of the limiting yield can differ across studies, ostensibly similar 'yield gap' studies may actually be measuring very different things. Thus, care must be taken in interpreting yield gaps – namely, it is important to understand exactly what is being measured. It has been shown empirically that different methods of estimating the limiting yield can produce markedly different results. For example, Singh *et al.* (2009) estimate state-level Indian yield gaps for several crops using both simulated yields and experimental yields as alternative measures of the limiting yield. In most

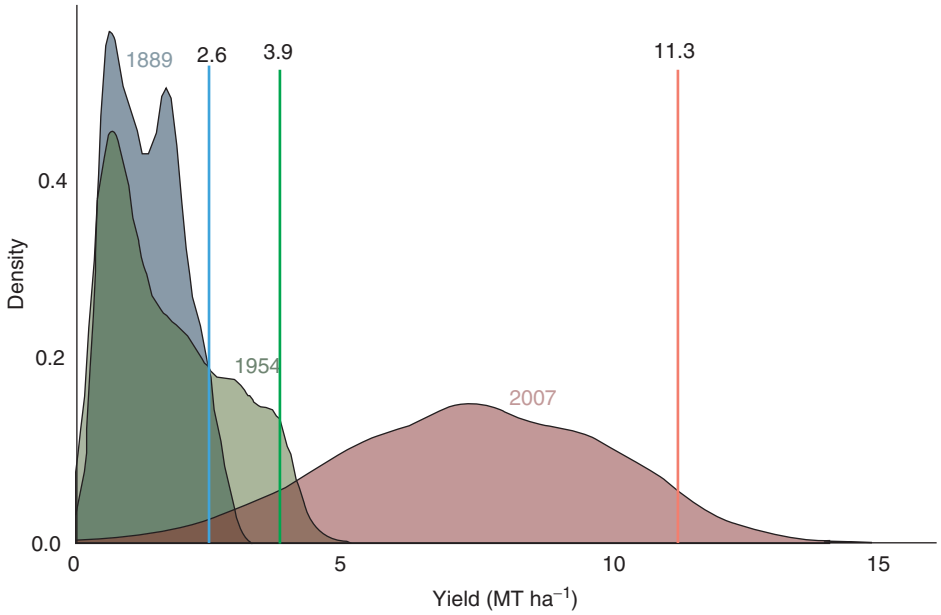

Figure 3 County-level maize yield distribution, 1889, 1954, and 2007. The limiting yield for each year was calculated as the 95th percentile of the unweighted county-level yields for all counties that harvested maize in the corresponding year. This limiting yield is shown as a vertical line for each distribution (with the value indicated at the top), in a color corresponding to the color of the distribution. Created by the authors using data from Beddow, J.M., 2012. A Bio-Economic Assessment of the Spatial Dynamics of U.S. Corn Production and Yields. Ph.D. Dissertation. Department of Applied Economics, University of Minnesota.

cases, the limiting yield implied by crop simulation models was markedly higher than the limiting yield implied by experimental results. Aggarwal *et al.* (2008) present a similar study including yield gaps derived using three methods to estimate the limiting yield: simulation models, experiments, and on-farm demonstrations.

Lack of standardization in the measurement of yields must also be carefully considered in the interpretation of yield gaps. This is particularly true when comparing yield gaps across farm versus landscape analyses, but is also true for comparisons across farm-level analyses or across landscape-level analyses. For example, global analyses of yield gaps rely on aggregate estimates of yields over geo-politically defined statistical regions. The mere process of this aggregation will tend to mute the spatial variability of yields and the size of yield gaps when compared with more disaggregate measures such as those constructed based on farm- or field-level yield observations. This can be illustrated using pixelated estimates of global maize yields on a 5 arc min (approximately 10×10 km) grid. (The production, area and yield data used for this illustration come from the Spatial Production Allocation Model 2000 v3.0.6 (You *et al.* 2000).) **Table 1** reports descriptive statistics for the global distribution of yield gaps calculated in two ways. The first distribution is based on the difference between the 95th percentile yield estimate for all pixelated yields within an agroecological zone (data for the agroecological zones are from Sebastian (2006)) and the pixelated yield estimate, which reflects yield gaps derived from disaggregate data and is to some extent analogous to using farm- or field-level yield estimates in a landscape-scale study of yield gaps. (Yield gap distributions were calculated using area weights as described in the Section Are Yields Gaps Good, Bad or Irrelevant?) The second distribution is based on the difference between the 95th percentile yield estimate for the country average yields in an agroecological zone and the country average yield for a pixel, which reflects yield gaps derived using methods analogous to those typically employed in landscape scale assessments of yield gaps. With the more disaggregated yield estimates, the mean, median, maximum, and standard deviation of the yield gap distribution are 65.2, 148, 44.7, and 8.5% higher, respectively, than with the country aggregated data. Therefore, simple differences in spatial aggregation across studies can result in noncomparable yield gap estimates.

The lack of standardization in the measurement of actual and limiting yields can lead to some confusion, particularly in the policy arena. Sumberg (2012) argues strongly that the yield gaps used in policy arguments are often specified such that they are as large as possible or that they justify the analyst's preferred policies, concluding with a warning that yield gaps are "seldom what they appear" (p. 517).

Yield Gaps with Multiple Enterprises

Diversification is a common strategy in farming used to manage risk and to better utilize lumpy assets and farm family labor resources for which different farm enterprises have different seasonal demands. It is accomplished by growing multiple crops, raising livestock in addition to crops, or being employed off as well as on the farm. With multiple enterprises, the allocation of scarce inputs to one enterprise inevitably affects the output in other enterprises. Van Ittersum *et al.* (2013) note that agronomically optimal sowing dates might not be economically optimal when multiple crops are planted each year (e.g., the optimal harvest date of one crop might conflict with the optimal planting date of a follow-on crop). Von Braun (1988) demonstrated that there may be complex interactions in multicrop systems, such that adoption of a yield-increasing technology for one crop may decrease yields of other crops Von Braun (1988) reported on the effects of an improved rice production scheme in The Gambia, finding that, on average, 390 kg of cereals and 400 kg of groundnuts are foregone for each additional ton of rice. This result was influenced both by the expected substitution of labor into the now more productive rice production along with a complex household and farming structure. Von Braun warns that "[t]he more complex the household structures and production organization in agriculture are, the less straightforward the predictions are on how technological change may impact on nutritional improvement (p. 1095)." The importance of such tradeoffs is not easily accounted for when focusing exclusively on individual crop yields and yield gaps.

Figure 4 illustrates how yield gaps emerge from a farmer's choice of activities. In the illustrated case, a farmer is allocating his (limited) time between maize production and off-farm work that pays an hourly wage. (The off-farm production example used here could easily be replaced by the production of an additional on-farm output, such as a second (or more) crop(s), with no change in the yield-gap implications of the example.) The shaded area shows the production possibilities for maize yields and off-farm work, given existing technology

Table 1 Descriptive statistics for disaggregated pixelated and aggregated country average yield gaps by agroecological zones (AEZ)

	Disaggregated pixelated yield gaps by AEZ (MT ha^{-1})	*Country aggregated yield gaps by AEZ (MT ha^{-1})*
Mean	3.81	2.30
Median	3.38	1.36
Standard deviation	2.58	2.38
Maximum	13.27	9.17
Minimum	0.0	0.0

Note: Disaggregated pixelated yield gaps were constructed as the difference between the 95th percentile of pixelated yields in an agroecological zone (AEZ) and the pixelated yield. Country aggregated yield gaps were constructed as the difference between the 95th percentile of the country average yield in an agroecological zone and the average yield of each country's constituent pixels.

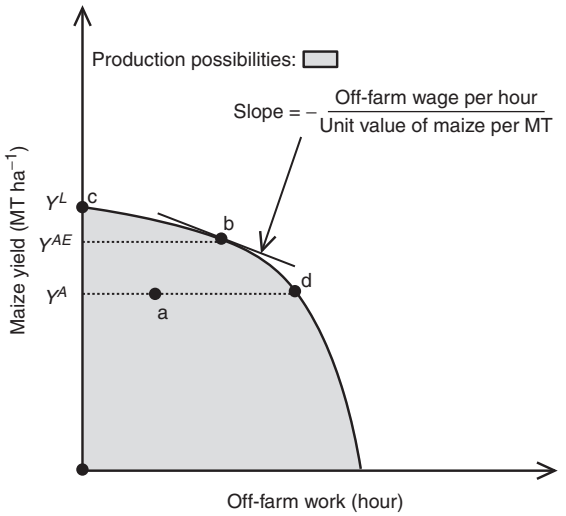

Figure 4 Hypothetical example of limiting, allocatively efficient, and actual yields when maize and off-farm work are produced.

and input constraints. The upper boundary of this region denoted by the solid curve is the PPF. Point a is inefficient because more maize can be produced without decreasing off-farm work (and thus, off-farm income) or more off-farm income could be acquired without decreasing maize production. Allocative efficiency requires equality between the value of an additional ton of maize and the value of the off-farm work that would be given up to produce the additional maize, which occurs where the slope of the PPF equals the negative of the ratio of the wage to the unit value of maize (point b). The negative sign reflects the fact that some maize must be given up to do more off-farm work when production is technically efficient.

The limiting yield, Y^L, occurs at point c where off-farm work is at a minimum so the farmer can devote as much time as necessary to the production of maize to maximize yield. The actual yield, Y^A, could be technically, but not allocatively, efficient (point d). Alternatively, it could be technically and allocatively inefficient (point a). The allocatively efficient yield corresponding to point b maximizes the sum of the value of maize production and off-farm work. The gap between the limiting and allocatively efficient yield is once again inevitable if off-farm work is valuable to the farmer, so trying to close it is not economical. Thus, yield gaps can emerge from economical choices over what to produce (e.g., maize or off-farm work) as well as over how it is produced (e.g., with more or less fertilizer). The gap between the allocatively efficient and actual yield is technically or allocatively inefficient because what the farmer is choosing to produce is wasteful given the value of maize and the wage rate.

Conclusion

Making progress on food security requires more than a biological view. Yields are lower or higher depending on the unit costs of inputs, the unit value of output, and other socioeconomic constraints faced by producers. An important economic constraint, particularly in low-income countries, is the inadequate state of transportation infrastructure. Poor road and rail networks increase the cost of getting output to markets and inputs to farms, and thus change the relative unit costs of inputs and the unit values of output at the farm gate, with (often negative) consequences for the allocatively efficient yield. Other constraints also hinder farmers: poor storage facilities require that output be sold rather than stored when market prices are low; trade restrictions can reduce domestic prices; and missing or poorly functioning markets for credit, insurance and labor all serve to reduce a farmer's allocatively efficient yield.

Yield gaps are the wrong metric if the primary concern is food security, which is fundamentally about the capacity of agriculture to supply affordable food efficiently and sustainably to subsistence farmers and nonfarm consumers alike. Closing yield gaps is neither necessary nor sufficient for improving food security. Indeed, as demonstrated above, a region's yield and output could improve even though yield gaps are increasing. Further, targeting the closure of yield gaps as a policy in order to feed more people may have unintended consequences. For example, idling either less-productive land (thus decreasing the gap directly) or idling the most productive land (thus reducing the limiting yield) would close the yield gap, but would also reduce total output. Output is the primary determinant of the availability and affordability of food, and efforts to increase output will tend to improve the lot of nonfarmers as well as farmers. Thus, in many cases, policies might best be focused on increasing the output of a region or the world as a whole – such as investments that enhance farmer productivity and participation in markets – rather than on simply decreasing yield gaps, which is not guaranteed to improve food security and often will be uneconomic.

Glossary

Adulterant A chemical substance deliberately added to food to deceive others in some manner.
Food toxicology The science that sets the limits of safety for chemical substances in foods.
Mycotoxin A potentially toxic chemical produced by molds growing on agricultural crops or foods.
Phycotoxin A potentially toxic chemical produced by dinoflagellate algae that is ingested by fish or shellfish.
Toxicology The science of poisons.

Introduction

Foods contain a myriad of chemicals, including the nutrients needed to sustain life. Food toxicology could be defined as the science that establishes the basis for judgments about the safety of foodborne chemicals. The central axiom of toxicology as set forth by Paracelsus in the 1500s states: "Everything is poison. Only the dose makes a thing not a poison." Thus, all chemicals in foods, whether natural or synthetic, inherent, adventitious, or added, are potentially toxic. Although all chemicals are toxic, many fewer pose a risk under typical circumstances of exposure, including the dose and frequency of exposure. The vast majority of foodborne chemicals are not hazardous because the amounts of each foodborne chemical in the typical diet are not sufficient to cause injury. The age-old wisdom about the benefits of eating moderate amounts of a varied diet protects most consumers from any harm. Foodborne chemicals that are considered to be toxicants are those chemicals where the dose and frequency of exposure can, in at least some circumstances, be sufficient to elicit adverse reactions. Unusual dietary practices can sometimes result in intoxications from chemicals that would normally be considered safe and desirable. Examples would include several of the polar explorers who experienced toxic responses to excessive intake of vitamin A as the result of consuming large amounts of polar bear liver and, more recently, the ingestion of copious quantities of water in a misguided radio contest that resulted in the death of a contestant.

Toxic reactions to food encompass all food-associated illnesses that are caused by chemicals in food. Foodborne chemicals vary greatly in toxicity. All consumers are susceptible to most food intoxications, although differences exist primarily related to the dose of exposure and body weight (infants vs. adults). Food allergies and metabolic food disorders, for example, lactose intolerance, are a subset of food intoxications that affect only certain individuals in the population. For the purposes herein, only those foodborne chemicals that are potentially hazardous to humans under known (though sometimes atypical) circumstances of exposure are discussed. These foodborne chemicals are divided into categories based on source – naturally occurring, food contaminants, processing-induced toxicants, and food additives. In recent decades, the science of food toxicology has emerged as an approach toward understanding and assessing the risks posed by the various chemicals in food.

Acute adverse reactions to foods are those adverse reactions occurring within hours to a few days following exposure to the particular foods/foodborne chemicals. Acute foodborne intoxications usually result in a rapid onset of symptoms. Chronic foodborne intoxications involve more prolonged exposures with symptoms that develop more slowly. With chronic toxicity, the attribution of the cause-and-effect relationship to a specific foodborne chemical is often quite difficult due to the existence of many confounding variables. The toxic characteristics of various foodborne chemicals are based either on investigations of incidents where humans developed adverse reactions (more often the situation with acute intoxications) or on the results of controlled feeding trials conducted with laboratory animals, usually rats or mice. In the following sections, examples of foodborne chemicals from various sources are described with the focus on examples of chemicals that do have a realistic potential of eliciting adverse reactions under at least some circumstances of exposure. Clearly, it is impossible to discuss all of the many thousands of chemicals in foods. The examples are selected because the toxic potential is recognized, although the listing is not intended to be comprehensive among chemicals fitting that criterion.

Food Additives

Food additives are chemical substances that are knowingly added to foods to provide a wide variety of technical benefits, including nutrients (Table 1). Thousands of food additives exist, although many are used in rather small amounts. In the United States, food additives can be classified on the basis of their regulatory status: (1) generally recognized as safe (GRAS) substances, (2) flavors and extracts, (3) direct additives, and (4) color additives. Because food additives are intentionally added to foods, these chemicals are carefully evaluated for safety often using feeding trials in laboratory animals. Only those chemicals that are shown nonhazardous under normal circumstances of exposure or those that have a long history of safe use are permitted to be used as food additives.

Many food additives were in common use long before the passage of comprehensive food laws, such as the 1958 Food, Drug and Cosmetic (FD&C) Act in the United States. These substances are considered as GRAS based on their history of safe use. More than 600 chemicals are on the US Food & Drug Administration (FDA) GRAS list, including sucrose, salt,

 doi:10.1016/B978-0-444-52512-3.00064-4

Table 1 Categories of food additives

Category	*Example*
Acidulents	Acetic acid
Anticaking agents	Magnesium silicate
Antimicrobial agents	Sodium benzoate
Antibrowning agents	Sodium bisulfite
Antioxidants	Butylated hydroxyanisole
Emulsifying agents	Lecithin
Nutrients	Ascorbic acid
Sequestrants	Citric acid
Stabilizers	Guar gum
Spices	Cinnamon
Oleoresins and extracts	Fennel oil
Flavorings	Ethyl butyrate
Enzymes	Glucose isomerase
Colorants, artificial	FD&C Yellow #5
Colorants, natural	Annatto
Sweeteners	Sucrose
Nonnutritive sweeteners	Aspartame

butylated hydroxytoluene, spices, and many nutrients. From a legal standpoint, GRAS substances are not actually additives, but that distinction is seldom made by the consumer. Although GRAS substances are considered to have a history of safe use, that does not necessarily imply that substantial toxicological data exist for all of these substances. New concerns can periodically arise regarding GRAS substances. For example, the concerns around sodium levels in the diet and hypertension ensued long after the placement of sodium chloride on the GRAS list. Substances, or certain uses of substances, can be removed from the GRAS list if the FDA acquires evidence of some hazard to consumers.

In addition, in the United States new substances can be affirmed as GRAS based on the judgment of a panel of expert scientists qualified by experience and training to make such judgments. In such GRAS affirmation situations, the experts evaluate the safety of the substance based on its characteristics, composition, history of safe use, and toxicological properties. A substance can be affirmed as GRAS based on a documented history of safe use or on the basis of scientific studies that are published in the peer-reviewed scientific literature. Substances are affirmed as GRAS for specific uses, thereby controlling exposure within the limits that might be imposed by the available evidence. The FDA is often notified of GRAS affirmation decisions and has the authority to object if it disagrees with the expert panel.

Internationally, the Joint Expert Committee on Food Additives of the World Health Organization periodically reviews the existing toxicological data on food additives, including long-standing food additives, and establishes Acceptable Daily Intakes (ADIs) for their use. ADIs can be readjusted as new information becomes available.

Flavors and extracts represent a large percentage of the total number of food additives. The Flavor and Extract Manufacturers Association (FEMA) keeps a list of accepted flavors and extracts. The FEMA has established a GRAS list for flavors and extracts and is largely responsible for evaluating the safety of the chemicals on the list; the FEMA has an expert panel that conducts the safety assessments of these chemicals. More than 1000 chemicals are on the FEMA list, although some of these chemicals and extracts are no longer used.

In the United States, direct food additives are those new chemicals that have been approved by the FDA since 1958. Few approvals for new food additives have been granted in recent years. Extensive and costly safety data are required to gain such FDA approval. Aspartame, a nonnutritive sweetener, is one of the most notable direct food additives in use in the United States (and many other countries). Aspartame was approved as a nonnutritive sweetener for certain types of uses some years ago and the consumption of this new additive has become substantial. More recently, Olestra, a noncaloric fat replacer, was approved for certain uses, such as the deep-fat frying of chips.

Color additives are regulated separately in the United States. Any new artificial color additive must be approved by the FDA in much the same way that new direct food additives are approved. Several artificial color additives have been banned since 1958 because of concerns about their possible chronic toxicity. A good example is FD&C Red #2, now banned in the United States but allowed in Canada and other countries. Conversely, FD&C Red #40 is allowed for use in the United States but banned in Canada.

The degree of hazard associated with the presence of additives in foods is quite low. The level of exposure to most food additives, especially flavoring ingredients, is rather low, which diminishes the potential hazard. Additionally, the oral toxicity of food additives tends to be extremely low, especially with regard to acute toxicity. Some concerns have arisen about the chronic toxicity of a few food additives, including saccharin, FD&C Red #2, cyclamate, and others. Furthermore, the safety of many additives is well established through controlled feeding trials conducted in laboratory animals. The toxicity of food additives is low but also well known, and exposure can be limited to levels far below any dose that would be hazardous. By contrast, the toxicity of naturally occurring chemicals in foods is often not known. With naturally occurring chemicals, concerns exist that hazards could exist under certain conditions of exposure.

Despite their long history of safe use and the existence of data from animal feeding trials, the safety of some food additives has been called into question. With FD&C Red #2 and cyclamate (a nonnutritive sweetener), the questions have revolved around evidence for weak carcinogenic activity in laboratory animals. FD&C Red #2 and cyclamate were banned in the United States as a result of such evidence. Other concerns also exist, such as the role of sugar in dental caries and abnormal behavioral reactions, the role of monosodium glutamate (MSG) in asthma, the role of aspartame in headaches and other behavioral and neurological reactions, and the role of Olestra in gastrointestinal complaints. The concerns range from acute toxicity, such as aspartame and headaches or MSG in asthma, to chronic toxicity, such as cyclamate and bladder cancer or sugar in dental caries. Although a detailed discussion of all these issues is beyond the scope of this article, it may suffice to say that many of these assertions have been questioned and remain controversial.

Several illustrative examples are discussed for food additives. For acute intoxications, the examples include situations involving adverse reactions occurring as a result of excessive

consumption of an additive, misuse of an additive by the processor or consumer, and abnormal sensitivities of certain types of consumers to specific food additives. With respect to chronic intoxications, saccharin is discussed briefly. Many other examples could be cited for chronic toxicity concerns, including cyclamate and FD&C Red #2.

Sorbitol and Hexitols

Sorbitol and various other hexitols are alternative sweeteners, frequently used in candies and chewing gum, because they do not support formation of dental caries. Dietetic food diarrhea has been associated with these polyol food additives and serves as a good example of intoxication resulting from the excessive consumption of a food additive. These sugar alcohols are not as easily absorbed as sugar, but they are equally as caloric as sugar, once absorbed. Because of their slow absorption, these sweeteners can cause an osmotic-type diarrhea if excessive amounts happen to be consumed. Several cases have been reported where consumers were ingesting more than 20 g of these sweeteners per day (Taylor and Byron, 1984; Taylor, 2002). The levels of hexitols or sorbitols used in foods vary, but in one case the ingestion of 12 pieces of hard candy over a short period of time provided 36 g of sorbitol and resulted in diarrhea (Taylor and Byron, 1984). Infants are more susceptible than adults to this osmotic diarrhea effect.

Sulfites

Sulfites (sodium and potassium metabisulfte, sodium and potassium bisulfite, sodium sulfite, and sulfur dioxide) are widely used as food additives that serve multiple important technological functions, including antimicrobial agent, inhibitor of enzymatic and nonenzymatic browning, and bleaching agent. A small percentage of the population is known to be highly sensitive to ingestion of sulfites that elicit asthma if sufficient doses are ingested (Taylor *et al.*, 2008).

Tartrazine (FD&C Yellow #5)

Tartrazine, also known as FD&C Yellow #5, is an approved artificial food color that has been widely used in foods and pharmaceuticals for many years. Ingestion of tartrazine is associated with adverse reactions (asthma and chronic hives) in a sensitive subpopulation of consumers (Lockey, 1959). However, unlike the situation with sulfite-induced asthma, the association of tartrazine in the provocation of asthma and chronic uriticaria is controversial. The effects noted in some studies could not be reproduced in others (Bush and Taylor, 2009). Both asthma and chronic urticaria are chronic illnesses whose symptoms tend to flare-up at unpredictable times. In some of the clinical trials on tartrazine, key pharmaceutical agents have been withdrawn from the human subjects before initiation of the tartrazine challenges. If the study is not designed carefully, the flare-up of the asthma or urticaria in such a trial could be due to either the administration of tartrazine or the withdrawal of the medication that controls symptoms. The plethora of poorly designed clinical trials on tartrazine has led several groups to conclude that tartrazine may not actually elicit asthma or chronic urticaria (Bush and Taylor, 2009; Stevenson, 2003).

Olestra™

Olestra, a fat replacer, received food additive approval more recently. Olestra is poorly absorbed and is not metabolized, so it does not provide the calories that would be obtained with fat in similar products. However, ingestion of Olestra has been associated with acute gastrointestinal complaints, including anal leakage in some consumers (Cheskin *et al.*, 1998). The prevalence and seriousness of such complaints is a matter of some controversy (Cheskin *et al.*, 1998). Obviously, many consumers occasionally experience postprandial gastrointestinal maladies that makes the association of such complaints with a particular ingredient rather challenging.

Saccharin

Saccharin was one of the first nonnutritive sweeteners approved for food use. Subsequently, high doses of saccharin were shown to cause bladder cancer in laboratory animals (Munro, 1989). However, the extrapolation of these results to humans, who typically ingest much lower levels of saccharin, has stimulated controversy. Thus, the carcinogenicity of saccharin to humans at typical levels of intake is, at best, uncertain, and saccharin remains on the market in the United States.

Niacin

Niacin is a nutritional additive widely and appropriately viewed as beneficial. But even nutrients can occasionally be associated with adverse reactions. In fact, the Dietary Reference Intakes developed by the U.S. National Academy of Science include tolerable upper intake levels for many of the common micronutrients (Food and Nutrition Board, 1998). Such intake levels are rarely exceeded with foods alone but can be exceeded with dietary supplements.

Excessive consumption of the B vitamin, niacin, can cause an acute onset of flushing, pruritis, rash, and burning or warmth in the skin, especially on the face and upper trunk (DiPalma and Ritchie, 1977), although gastrointestinal discomfort is noted in some patients (Press and Yeager, 1962). Outbreaks have occurred from the excessive enrichment of flour used to make pumpernickel bagels (Campana *et al.*, 1983) or corn meal (Press and Yeager, 1962). These episodes occurred as a result of inaccurate or inadequate labeling of food ingredient containers. The amount of niacin required to elicit such adverse reactions is at least 50 times the recommended dietary allowance (RDA) (Campana *et al.*, 1983; Press and Yeager, 1962). The symptoms of niacin intoxication are acute, self-limited, and without sequelae.

Vitamin A

Vitamin A is also a nutrient additive with well-documented benefits. But excessive intake can elicit adverse reactions. In addition to the example with polar bear liver, the toxicity of

vitamin A can also be illustrated by other more conventional, but also unwise, dietary choices. Vitamin A intoxication occurred in twin infants who were provided a diet consisting largely of pureed chicken livers, pureed carrots, milk, and vitamin supplements (Taylor, 2002). Apparently, the mother of these infants initiated this diet because of her distrust of commercial baby foods. After ingesting this diet for several weeks, both infants began to vomit and developed a skin rash. The symptoms disappeared with institution of a more normal diet. The estimated intake of vitamin A and carotene was 44 000 IU per day compared with the RDA of 1500–4500 IU per day for infants.

Intentional Food Adulterants

Although food additives either have a history of safe use or have been assessed for safety and are approved for use in foods by some regulatory agencies, chemical food adulterants are not approved and their addition is illegal and unscrupulous. Adulterants have not been tested for safety or have not had a long history of safe use. Thus, adulterants have a much higher potential to be hazardous. Although many examples exist from ancient to modern times regarding intentional adulteration of foods (Everstine *et al.*, 2013), a few noteworthy examples, including the toxic oil syndrome, that occurred in Spain several decades ago, the more recent melamine adulteration of infant formula and pet foods in China, and the more mysterious pine mouth syndrome are described here.

Toxic Oil Syndrome

In Spain, in the early 1980s, an epidemic occurred involving more than 10 000 cases and more than 300 deaths that were ultimately linked to the ingestion of unlabeled, illegally marketed cooking oils (Kilbourne *et al.*, 1983; Posada de la Paz *et al.*, 1996). The illicit cooking oil contained denatured oil that was intended for industrial rather than food uses. Apparently, the denaturing process caused the formation of some chemical substance(s) that was responsible for the syndrome. The causative toxin in the oils remains unknown. Fatty acid anilides resulting from the denaturation process are suspected to be at least partially responsible (World Health Organization, 1992).

Toxic oil syndrome was associated with a range of clinical manifestations involving multiple organ systems (World Health Organization, 1992). In the initial phase of the illness, affected individuals experienced fever, chills, headache, tachycardia, cough, chest pain, and pruritis. Physical examinations revealed various skin exanthema, splenomegaly, and generalized adenopathy. Pulmonary infiltrates were noted in 84% of the affected individuals, probably as the result of increased capillary permeability. The intermediate phase of the illness persisted from the second week after onset through the eighth week postingestion and involved gastrointestinal symptoms, primarily abdominal pain, nausea, and diarrhea. At this stage, marked eosinophilia was apparent in 42% of patients accompanied by high IgE levels, thrombocytopenia, abnormal coagulation patterns, and evidence of hepatic dysfunction with abnormal enzymes. Some individuals became jaundiced, and many had hepatomegaly. The late phase of the illness developed in 23% of cases and began after 2 months of illness. The late phase was initially characterized by neuromuscular and joint involvement with later development of vasculitis and a scleroderma-like syndrome. Affected individuals complained of intense muscular pain, edema, and progressive muscular weakness. Some individual experienced muscular atrophy. Neurological involvement included depressed deep tendon reflexes, anesthesia, and dysesthesia. Respiratory problems developed due to neuromuscular weakness and progressed to pulmonary hypertension and thromboembolic phenomena. The scleroderma-like symptoms included Raynaud's phenomenon, sicca syndrome, dysphagia, and contractures due to thickening skin collagen. Vascular lesions were noted in all organs apparently resulting from endothelial proliferation and thrombosis. In the late phase, all patients had antinuclear antibody, and many had antibodies against smooth muscle and skeletal muscle (Rodriguez *et al.*, 1982). These pathological and clinical features point to an autoimmune mechanism for the illness. Since the precise causative agent has not been identified, the prevention of future recurrences of toxic oil syndrome is more difficult to assure. Furthermore, it is unknown whether the toxin might be present in small amounts in other foods and thus might be producing or aggravating other clinical conditions.

Melamine

Melamine (2,4,6-triamino-1,3,5-triazine, **Figure 1**) has been used as an industrial chemical for the manufacturing of plastics, adhesive, fabrics, and flame retardants for many years. Melamine was used as an intentional adulterant of pet foods and dairy products, including infant formula several years ago in China to increase the 'apparent' protein content of these products (Dobson *et al.*, 2008; Ingelfinger, 2008). When analytical methods for nitrogen determination, such as the Kjehdahl and Dumas methods, are used for estimating the protein content of foods, melamine gives a strong positive result. In 2007, wheat gluten from China was adulterated with melamine and that wheat gluten was subsequently used in North America to manufacture pet foods. Because of the exposure to melamine and the related substance, cyanuric acid, a large number of pets suffered renal toxicity and renal failure; many pet dogs and cats died as a result (Dobson *et al.*, 2008). When melamine and cyanuric acid are consumed together, crystals of melamine cyanurate form readily in the kidney tubules leading to acute renal failure (Dobson *et al.*, 2008). The second known instance of melamine adulteration in China occurred in 2008, involving infant formula and other milk products; cyanuric acid was not detected in this episode. As many as 294 000 infants and young children in China were affected by the

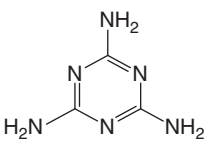

Figure 1 Structure of melamine.

contaminated formula and dairy foods (Ingelfinger, 2008; Wu and Zhang, 2013) leading to 50 000 hospitalizations and at least 6 fatalities. As in the pet food episode, renal toxicity was the primary manifestation. Apparently, melamine alone under some conditions can also lead to the formation of crystals in the renal tubules leading to nephrolithiasis (Wu and Zhang, 2013).

Pine Mouth Syndrome

Pine nuts have been regularly consumed in many countries, although their popularity in North America has increased over the past decade. The Food and Agricultural Organization of the United Nations (FAO) has recognized a list of several dozen species of pine trees that can be considered as suitable sources of pine nuts for food use. Recently, rare cases of an illness called pine mouth syndrome have been reported (Munk, 2012). In this unusual syndrome, affected consumers report losing their sense of taste for several days to weeks after the ingestion of pine nuts. The substance responsible has not yet been identified. However, evidence has emerged that pine nuts from pine trees that are not on the FAO list are implicated in these incidents. Although these incidents are not as deliberate as the toxic oil syndrome or melamine adulteration, pine mouth syndrome serves as a good example of the unintended consequences that can ensue from the use of foods or ingredients that are not well documented as suitable for food use.

Food Contaminants

Foods may also be contaminated with potentially hazardous chemicals from a variety of sources, including natural contaminants, agricultural chemicals, industrial contaminants, and processing-induced contaminants. Mycotoxins from molds, phycotoxins from marine algae, and bacterial toxins serve as the primary categories of natural contaminants. Other contaminants are manmade chemicals that have useful purposes, although they are not intended to occur in foods. These contaminants can include both agricultural and industrial chemicals.

Agricultural Chemicals

Many chemicals are used in modern agricultural practices for a variety of purposes, including insecticides, herbicides, fungicides, fertilizers, and veterinary drugs including antibiotics. Residues of these agrichemicals can be present in raw and processed foods. Public health agencies in various countries evaluate the safety of such chemicals and regulate and monitor their use on plant food products and in food-producing animals (Taylor, 2002).

Insecticides

Insecticides are applied to crops to control insect pests. Several categories of insecticides are used, including organochlorine compounds (dichlorodiphenyltrichloroethane (DDT), chlordane, and others – many of which are now banned), organophosphate compounds (e.g., parathion and malathion), carbamate compounds (e.g., carbaryl and aldicarb), botanical compounds (e.g., nicotine and pyrethrum), and inorganic compounds (e.g., arsenicals).

Low residual levels of insecticides occur in foods. Accordingly, insecticide residues in foods are not particularly hazardous, especially on an acute basis when these chemicals are used properly. Certainly, large doses of insecticides can be hazardous to humans. Several categories of insecticides, such as the organophosphates and carbamates, are neurotoxic. These chemicals are cholinesterase inhibitors and act by blocking synaptic nerve transmission. However, these chemicals dissipate quickly in the environment. Thus, the primary risk involves agricultural workers (pesticide applicators) and that risk can be minimized by use of appropriate protective measures. Insecticide residues in foods pose a low degree of hazard for several reasons: (1) the level of exposure is very low, (2) some insecticides are not very toxic to humans, (3) some insecticides decompose rapidly in the environment, and (4) many different insecticides are used, which limits exposure to any one particular insecticide (Taylor, 2002). Most of the rather rare acute food poisoning episodes attributable to pesticide have resulted from the misuse of pesticides, including contamination of foods during storage and transport, the use of pesticides in food preparation due to their mistaken identity as common food ingredients such as sugar and salt, and their misuse in agricultural practice on crops for which they are not intended to be used (Ferrer and Cabral, 1991).

The agricultural misuse of aldicarb serves as one of the best examples of an acute food poisoning episode associated with pesticides. An outbreak of aldicarb intoxication from watermelons occurred on the West Coast in 1985 (Green *et al.*, 1987). However, the use of aldicarb on watermelons is actually illegal because excessive levels of aldicarb become concentrated in the edible portion of the melon. In this episode, several farmers misused aldicarb by applying it to watermelons. Subsequently, consumers became acutely ill from eating those watermelons. The illegal aldicarb residues were discovered, leading to a watermelon recall and the destruction of thousands of watermelons. The outbreak involved a total of 1373 illness reports with 78% classified as probable or possible aldicarb poisoning cases, making this episode the largest known outbreak of pesticide poisoning in North America (Green *et al.*, 1987; Goldman *et al.*, 1990). The symptoms of aldicarb intoxication include nausea, vomiting, diarrhea, and mild neurological manifestations, such as dizziness, headache, blurred vision, and loss of balance (Green *et al.*, 1987; Goldman *et al.*, 1990; Goes *et al.*, 1980). Although the watermelon episode was larger, aldicarb has also been involved in a smaller outbreak associated with the ingestion of hydroponically grown cucumbers (Goes *et al.*, 1980).

Although acute intoxications from insecticide residues in foods are rare, long-standing concerns have been raised about the possible chronic toxicity associated with pesticide residues in foods (Concon, 1988). DDT, for example, is a known animal carcinogen. Furthermore, organochlorine insecticides, such as DDT, are quite persistent in the environment and have been associated with undesirable environmental consequences, including eggshell thinning in birds. Because of the

health and environmental concerns, many organochlorine pesticides have been banned or allowed for use only under very restricted conditions. Despite the concerns, the evidence that the low residual amounts of insecticides on foods present a carcinogenic risk to human consumers is not particularly strong.

Recently, genetically engineered, insect-resistant crops, especially corn, have been developed. These crops contain a novel gene that produces a naturally occurring insecticidal protein toxin from *Bacillus thuriengensis* (Bt). Bt toxins have been externally applied to crops, especially in organic agriculture for decades. In the case of the genetically engineered Bt corn, the Bt proteins are expressed within the corn plant. The Bt proteins produced by the genetically engineered crops have been thoroughly examined and appear to be quite safe for human consumption (Sanders *et al.*, 1998).

Herbicides

Several categories of herbicides are applied to agricultural crops to control the growth of weeds, including chlorophenoxy compounds (e.g., 2,4-D), dinitrophenols (e.g., dinitroorthocresol), bipyridyl compounds (e.g., paraquat), substituted ureas (e.g., monuron), carbamates (e.g., propham), and triazines (e.g., simazine).

Herbicides tend to be selectively toxic to plants or even certain types of plants. Consequently, herbicide residues in foods do not present any hazard to consumers in the vast majority of circumstances. Food poisoning incidents have never resulted from the proper use of herbicides on food crops. The lack of hazard from herbicide residues is associated with the low level of exposure, their low degree of toxicity to humans and selective toxicity toward plants, and the use of many different herbicides that limits exposure to any particular herbicide (Taylor, 2002).

Although most herbicides are selectively toxic to plants, the bipyridyl compounds are an exception. The bypryridyl herbicides including diquat and paraquat are not selectively toxic to plants and are actually rather toxic to humans. In humans, the bipyridyl herbicides tend to exert their toxic effects on the lungs (Taylor *et al.*, 1992). However, no food poisoning incidents have ever been attributed to inappropriate use of the bipyridyl compounds.

Fungicides

Fungicides curtail the growth of molds on food crops. Important fungicide categories include captan, folpet, dithiocarbamates, pentachlorophenol, and the mercurials. The hazards from foodborne fungicides are miniscule because exposure is quite low, most fungicides do not accumulate in the environment, and fungicides are typically not very toxic (Taylor, 2002). However, the mercurial compounds and hexachlorobenzene are exceptions and do present some risk to consumers in certain circumstances.

Mercurial fungicides are often used to treat seed grains to prevent mold growth during storage. Seed grains treated with mercurial fungicides are typically colored pink and are intended solely for planting. However, especially in times of famine, consumers are tempted to eat the seed grain. On the occasions where consumers have eaten these mercury-treated seed grains, they have developed mercury poisoning sometimes even resulting in deaths (Ferrer and Cabral, 1991). Mild cases of mercury intoxication are more typical and are manifested in gastrointestinal symptoms, such as abdominal cramps, nausea, vomiting, and diarrhea, and dermal symptoms, such as acrodynia and itching (Ferrer and Cabral, 1991).

Hexachlorobenzene is another fungicide used to treat seed grains to prevent mold growth during storage. A massive outbreak of hexachlorobenzene poisoning affecting more than 3000 individuals occurred in Turkey between 1955 and 1959 (Schmid, 1960). This incident is the most massive outbreak of pesticide poisoning in recorded history. In this episode, the symptoms were quite severe with a 10% mortality rate, porphyria cutanea tarda, ulcerated skin lesions, alopecia, porphyrinuria, hepatomegaly, and thyroid enlargement (Schmid, 1960).

Fertilizers

Fertilizers are widely applied to agricultural crop land and are typically combinations of nitrogen and phosphorus compounds. Nitrogen fertilizers are oxidized to nitrate and nitrite in the soil. Both nitrate and nitrite are hazardous to humans, especially infants, if ingested in large amounts (Taylor, 2002). Fertilizers typically present little, if any, risk to consumers. However, some plants, including spinach, can accumulate nitrate to hazardous levels if allowed to grow on overfertilized fields (Fassett, 1973). Because nitrite is more toxic than nitrate, the situation worsens if nitrate-reducing bacteria are allowed to proliferate on these foods. As an example of the effects of nitrate-reducing bacteria, an incident occurred with carrot juice that was improperly stored allowing the proliferation of nitrate-reducing bacteria and the accumulation of hazardous levels of nitrite (Keating *et al.*, 1973). In low doses, the symptoms of nitrite toxicity include flushing of the face and extremities, gastrointestinal discomfort, and headache; in larger doses, cyanosis, methemoglobinemia, nausea, vomiting, abdominal pain, and collapse can occur (Fassett, 1973). Death can result with an estimated lethal dose of nitrite of approximately 1 g in adults (Fassett, 1973).

Veterinary Drugs and Antibiotics

Veterinary drugs are used to treat a variety of conditions in food-producing animals. If properly used, the levels of veterinary drug residues in foods will typically be quite low, and acute food poisoning incidents would not have occurred as a result of properly used veterinary drugs and antibiotics (Taylor, 2002). However, concerns have arisen especially with respect to the use of antibiotics. Penicillin, a common antibiotic used in both veterinary and human medicine, serves as a good example. Some consumers are allergic to penicillin, having been sensitized as a result of its use in human medicine. Are penicillin-allergic consumers at any risk from exposure to penicillin residues that might exist in the food products obtained from penicillin-treated animals? The likelihood of allergic reactions to the very low levels of penicillin

residues found in animal food products is quite remote (Dewdney and Edwards, 1984).

Chemicals Migrating from Packaging Materials and Containers

Foods are often packaged for convenience, shelf stability, and protection from microbial pathogens and insects. Food packages and containers are made from chemical components. Under certain circumstances, some of these chemicals can migrate from the packaging material into the edible portion of the foods. A variety of chemicals, including plastic monomers, plasticizers, stabilizers, printing inks, and others, do migrate at extremely low levels into foods, but these packaging migrants do not typically pose a significant hazard to consumers. Heavy metals, including lead, zinc, tin, and others, can pose a hazard to consumers under certain circumstances (Hughes *et al.*, 1977). More recently, concerns have arisen about the potential chronic toxicity of bisphenol A migrating from packaging materials into foods (NTP-CERHR, 2008).

Bisphenol A

Bisphenol A (BPA) is a monomer used in the manufacture of plastics. BPA has been used in the production of polycarbonate resins for baby bottles and water bottles and in the epoxy resins used as the internal linings of cans for soft drinks and beer. Residues of BPA can migrate into foods and beverages stored in containers containing BPA (NTP-CERHR, 2008). The National Toxicology Program (NTP) in the United States has indicated that some concerns exist for adverse effects on the brain, behavior, and prostate glands in fetuses, infants, and children at current BPA exposure levels (NTP-CERHR, 2008). Considerable debate exists relative to the magnitude of the risk associated with these levels of exposure and little concern exists for any risk to exposed adults. However, efforts are being made to lessen the extent of exposure to BPA, although the safety and efficacy of alternative products are also of concern.

Lead

Environmental exposure to lead has been a persistent and significant public health concern. However, exposure to lead via foods as a percentage of the overall environmental exposure to lead has always been comparatively modest. Historically, the migration of lead from Pb-soldered cans was a source of some concern, but Pb-soldered cans have been successfully and completely phased out of use in the United States. But some concerns remain, principally the occasional use of lead-based glazes on pottery or paint on glassware that may come in contact with acidic foods or beverages. The acid leaches lead from the glaze or paint into the food or beverage. Lead is a well-known toxicant that can affect the nervous system, kidney, and bone.

Tin

The metal cans used for food storage are primarily constructed from tin plate. These inner surfaces of the tin plate cans are lined with a lacquer material when the cans are used for acidic foods or beverages. If unlacquered cans happen to be used for acidic food products, such as tomato juice or fruit cocktail, tin can be leached into the food or beverage, resulting in cases of acute tin intoxication (Barker and Runte, 1972). Tin is poorly absorbed, so the primary symptoms occur in the gastrointestinal tract (bloating, nausea, abdominal cramps, vomiting, and diarrhea) and occur 30 min to 2 h after consumption of the acidic product (Barker and Runte, 1972).

Zinc

Galvanized containers are inappropriate for the storage of acidic foods or beverages because zinc can leach into the food or beverage, resulting in acute zinc intoxication (Hughes *et al.*, 1977; Brown *et al.*, 1964). Fruit punch and tomato juice have been involved in zinc intoxication episodes (Hughes *et al.*, 1977). Zinc is a potent emetic. The symptoms of zinc intoxication include irritation of the mouth, throat, and abdomen; nausea; vomiting; dizziness; and collapse (Taylor, 2002).

Industrial Chemicals

Occasionally, industrial and environmental pollutants can migrate into foods. Usually, the amounts are rather small and inconsequential from a health perspective. However, the potential exists for hazardous levels of such chemicals to enter the food supply on rare occasions and these incidents can have devastating consequences from both a health and economic perspective.

Polychlorinated Biphenyls and Polybrominated Biphenyls

Polychlorinated biphenyls (PCBs) are frequently used in transformer fluid, whereas polybrominated biphenyls (PBBs) are commonly used as fire retardants. PCBs and PBBs are quite persistent in the environment and are considered as toxic pollutants from industrial practices. These compounds are fat soluble so they tend to accumulate in the fat depots of various organisms; concentrations often magnify upward along the food chain. PCBs and PBBs are not particularly worrisome as acute toxicants. However, because PCBs and PBBs are deposited in adipose tissue, they are only very slowly eliminated from the body. Thus, the chronic effects of exposure to these contaminants in foods are of concern. Food contamination with PCBs and PBBs has occurred on several occasions (Taylor, 2002). PBBs were involved in an infamous industrial contamination incident that involved the accidental contamination of dairy feed in Michigan (Fries, 1985). As PBBs are fat soluble, they would tend to accumulate in fat-containing foods, including whole milk. The incident resulted in the destruction of many cows and their milk. Although some consumers were most likely exposed in the early stages of this incident, no health consequences have been clearly linked to the incident. However, the economic impact was considerable. With PCBs, the most noteworthy incident did involve cases of human illness. The PCB incident was associated with the consumption of contaminated rice bran oil in Japan (Kuratsune *et al.*, 1972). The rice bran oil was contaminated

from a leaking heat exchanger that was used to deodorize the oil. The resulting syndrome was called yusho (meaning 'oil disease') by the Japanese. Yusho was characterized by chloracne, weakness, numbness of limbs, swelling of eyelids, discharges from the eyes, dark skin pigmentation, and liver damage (Kuratsune *et al.*, 1972; Higuchi, 1976). The acute symptoms were evident at exposure doses as low as 0.5 g, but chronic effects were noted in many of the victims and persisted for up to 8 years or more following exposure. The chronic symptoms included chloracne, menstrual disturbances, fatigue, headache, fever, cough, digestive disturbances, and numbness of the extremities (Kuratsune *et al.*, 1972; Higuchi, 1976). Because of the widespread use of PBBs and PCBs, industrial contamination incidents have the potential to continue to occur periodically. Hopefully, few will have the human toll experienced in the yusho episode.

Mercury

Another classic example of food contamination from industrial pollutants was the Minamata episode that also occurred in Japan. The Minamata disease episode occurred over a number of years and resulted from an industrial firm located on the shores of Minamata Bay in Japan that dumped mercury-containing wastes into the bay from 1953 until the early 1960s. Bacteria in the bay sediment converted the inorganic mercury into highly toxic, organic methylmercury. Elemental mercury is poorly absorbed from the gastrointestinal tract, whereas organomercury compounds, including methylmercury, are much more efficiently absorbed and are thus more toxic as food contaminants. The human illnesses occurred from consumption of fish from the bay that had become contaminated with methylmercury. More than 1200 cases of mercury intoxication occurred among consumers of Minamata Bay fish (Kurland *et al.*, 1960). The symptoms of mercury intoxication include tremors, other neurotoxic effects, and kidney failure.

Gulf of Mexico Oil Spill

In 2010, a massive oil spill occurred in the Gulf of Mexico from a ruptured oil well. As the Gulf of Mexico is a very rich source of seafood, concerns arose about contamination of various seafood products with the oil and its component chemicals (Genauldi *et al.*, 2013). Seafood harvests were temporarily halted. No illnesses were documented. However, economic consequences were considerable and demonstrate that even the threat of food contamination with industrial pollutants can be disruptive. Many challenges exist for assessment of the risk/safety of seafoods after an oil spill (Genauldi *et al.*, 2013; Gilroy, 2000).

Natural Contaminants

Natural sources such as toxigenic bacteria, mycotoxin-producing molds, and phycotoxin-producing algae are among the contaminants that have the greatest impact on human health.

Bacterial Toxins

Pathogenic bacteria typically cause foodborne disease by the infectious route. The mechanism of foodborne infectious disease involves invasion of cells and tissues, multiplication, and symptoms occurring as a result of cellular injury, inflammation, and disturbance of key physiological processes. Foodborne infectious agents should be viewed as distinct from food toxicology because the causative agents are living microorganisms. However, some foodborne bacteria are toxigenic and produce exogenous toxins in foods before they are eaten. The ingestion of these toxins initiates the disease process even if the bacteria are destroyed in processing or preparation. Thus, bacterial toxins are properly discussed as part of food toxicology. Several examples of bacterial intoxications are the staphylococcal enterotoxins, the botulinal toxins, histamine, and tetrodotoxin.

Staphylococcal Enterotoxins

The staphylococcal enterotoxins are produced in foods by certain strains of *Staphylococcus aureus* (Hennekinnie *et al.*, 2012) that grow on foods under certain conditions such as temperature between 10 and 45 °C and produce the enterotoxin during growth. Ingestion of the staphylococcal enterotoxins causes nausea and vomiting with a rapid onset time of 1–6 h. Staphylococcal food poisoning is a very common form of foodborne disease. The provoking dose of the staphylococcal enterotoxins is quite low, as ingestion of low microgram levels is sufficient to elicit symptoms (Hennekinnie *et al.*, 2012). Nine distinct, but structurally related, types of enterotoxins have been identified as being produced by various strains of *S. aureus* (Balaban and Rasooly, 2000). The staphylococcal enterotoxins are small proteins with molecular weights of 25 000–29 000 Da. On ingestion, the staphylococcal enterotoxins are resistant to digestion and are able to enter the small intestine without much hydrolysis. The enterotoxins bind to some as yet unidentified sites in the small intestine and transmit a signal to the vomiting center in the brain. The enterotoxins are quite heat resistant. Accordingly, staphylococcal food poisoning is often associated with foods cooked after improper storage that allowed the proliferation of *S. aureus* and enterotoxin production.

Botulism

Botulinal toxins are potent neurotoxins produced in foods under anaerobic conditions during growth of *Clostridium botulinum* (Parkinson and Ito, 2002). Toxin formation occurs in underprocessed canned foods. The commercial canning process is predicated on the destruction of *C. botulinum* and its spores so that the spores will not germinate, grow, and produce toxin on storage of the canned product. Canned foods are especially susceptible because of the anaerobic conditions. Seven different toxin-producing strains of *C. botulinum* have been identified, but types A, B, and E are the strains most commonly associated with foodborne illness (Parkinson and Ito, 2002). The botulinal toxins are proteins with a molecular mass of approximately 150 kDa (Parkinson and Ito, 2002). The botulinal toxins exert their neurotoxic effect by inhibiting the release of acetylcholine at the nerve synapses. Thus, the

peripheral nervous system is affected. Botulinal toxins are among the most potent toxins known to humans. In cases of botulism, clinical symptoms begin to develop 12–48 h after exposure to the toxin with weakness, dizziness, and mouth dryness occasionally accompanied by nausea and vomiting. Neurological symptoms follow, including blurred vision, inability to swallow, aphasia, and weakness of the skeletal muscles. Symptoms can ultimately progress to respiratory paralysis and death. The vegetative cell of *C. botulinum* and the botulinal toxins are easily destroyed by heat, but the spores are heat resistant. When thermal processing (canning) is not properly performed, spores will survive, germinate, and grow if suitable anaerobic conditions exist (Parkinson and Ito, 2002).

Infant botulism is a different but related illness where the spores enter the gastrointestinal system early in life before competitive intestinal microflora are in place to resist their germination and growth (Parkinson and Ito, 2002). The growth of *C. botulinum* ensues in the intestinal tract. Toxin production then occurs in the intestinal tract of the infant and causes severe illness. Infant botulism is avoided by limiting the intake of spores by infants. Honey is a frequent source of the spores in the infant diet (Parkinson and Ito, 2002).

Bacillus cereus Toxins

Bacillus cereus is a spore-forming microorganism capable of producing two types of toxins: emetic and diarrhetic (Schoeni and Wong, 2005). *Bacillus cereus* typically grows in foods, such as rice, soups, and sauces, that are stored improperly at elevated temperatures after cooking. The emetic toxin causes nausea and vomiting with an onset time of 30 min to 6 h after ingestion. The diarrhetic toxin causes abdominal cramping and diarrhea with an onset time of 6–15 h after ingestion.

Histamine or Scombroid Fish Poisoning

Histamine poisoning is an allergy-like intoxication most frequently associated with ingestion of certain types of fish from the families Scomberesocidae and Scombridae, such as tuna, skipjack, mackerel, and bonito (Hungerford, 2010). Hence, the syndrome is often called scombroid fish poisoning. However, scombroid fish poisoning is a bit of a misnomer because certain types of nonscombroid fish are also commonly involved, including mahi-mahi, bluefish, jack mackerel, sardines, yellowtail, anchovies, and herring. Cheese can also occasionally be involved, especially Swiss cheese. Histamine poisoning occurs on a worldwide scale with several hundred cases reported annually to public health agencies (Hungerford, 2010).

Histamine formation in foods is associated with the growth of bacteria possessing the enzyme histidine decarboxylase that is able to convert the amino acid histidine into histamine. Few bacterial species are capable of prolific histamine formation necessary to develop hazardous levels food products. In fish, *Morganella morganii* is often implicated. In fish, histamine formation occurs when fish are not properly frozen or refrigerated. In cheese, histamine formation is associated with the growth of certain species of lactobacilli (Sumner *et al.*, 1985). Swiss cheese is susceptible because milk is often not pasteurized before making that type of cheese.

The symptoms of histamine poisoning resemble those experienced during an allergic reaction. As histamine is a primary mediator released from mast cells during IgE-mediated allergic reactions, the reasons for the similarities are obvious. Gastrointestinal symptoms, such as nausea, vomiting, diarrhea, and abdominal cramps, are common. Tingling, itching, and burning sensations often occur in the mouth. Cutaneous symptoms, including flushing, urticaria, angioedema, and other itchy rashes, appear as well. Hypotension is a common manifestation. Other common symptoms include headache and palpitations. Symptoms of histamine poisoning typically appear within minutes to a few hours after ingestion of the offending food. Histamine intoxication is a self-limited illness and symptoms usually subside within a few hours even without treatment. Treatment with antihistamine drugs leads to prompt resolution.

Tetrodotoxin or Pufferfish Poisoning

Tetrodotoxin poisoning is associated with the ingestion of pufferfish, also sometimes known as blowfish, which belongs mostly to the genus *Fugu* (Hwang and Noguchi, 2007). Because of the frequently encountered toxicity of pufferfish, these species are not allowed for commercial sale in some countries. Pufferfish poisoning occurs primarily in Japan and China, because those are the primary areas of the world where pufferfish are frequently consumed and considered as a delicacy (Hwang and Noguchi, 2007). Although more than 30 species of pufferfish are found worldwide, most species are not considered to be toxic (Taylor, 1988) perhaps because the toxin is episodically present. The toxin is a potent neurotoxin called tetrodotoxin (Taylor, 1988; Hwang and Noguchi, 2007). For many years, tetrodotoxin was thought to be produced by the fish. More recently, new evidence suggests that marine bacteria may be the original source of the toxins (Yasumoto *et al.*, 1986). Tetrodotoxins are heat stable and, like the saxitoxins, act by blocking the sodium channels in nerve cell membranes (Taylor, 1988). The symptoms of tetrodotoxin poisoning usually begin with a tingling sensation of the fingers, toes, lips, and tongue, followed by nausea, vomiting, diarrhea, and epigastric pain progressing to twitching, tremors, ataxia, paralysis, and sometimes death (Mines *et al.*, 1997). A fatality rate of approximately 60% occurs in untreated cases (Mines *et al.*, 1997). The tetrodotoxins accumulate in the liver, viscera, and roe of the pufferfish. Careful cleaning of the fish, before ingestion of the edible muscle, safeguards against tetrodotoxin intoxication (Taylor, 1988). Although tetrodotoxin was once thought to be a single chemical entity (Taylor, 1988), it is now recognized that various bacteria which belong to species such as *Altermonas*, *Vibrio*, and others can produce different but related forms of tetrodotoxin that vary in potency (Yasumoto *et al.*, 1986). Even though tetrodotoxin poisoning is primarily associated with *Fugu* fishes, similar if not identical toxins occur in newts, frogs, marine snails, octopuses, crabs, starfishes, and other marine species (Wakely *et al.*, 1966).

Mycotoxins

A wide variety of molds exist in the environment and many of these molds can grow on foods. Some of the foodborne molds

are able to produce toxic substances called mycotoxins as they grow on foods (Richard, 2007). The toxic properties of mycotoxins are recognized either from their effects on humans or on one or more economically important animal species. In some cases, the toxicity of the mycotoxins has not been clearly established in humans, whereas with others, the toxicity to humans is clearly documented. Aflatoxins and fumonisins serve as the primary examples, although many other mycotoxins have also been identified in foods.

The aflatoxins are produced by certain species of *Aspergillus* molds, primarily by *Aspergillus flavus* and *Aspergillus parasiticus*, molds that often contaminate peanuts and corn (Richard, 2007). Aflatoxins B and G are the forms that have been identified in legumes and cereals. Dairy cows fed aflatoxin-contaminated grains or oilseeds are known to have a related form of aflatoxin, aflatoxin M, in their milk. The aflatoxins are potent carcinogens, especially affecting the liver (Richard, 2007). The significance of aflatoxins in human carcinogenesis remains uncertain, although humans with preexisting liver conditions, such as hepatitis, appear to be among the most susceptible. Aflatoxins are among the most potent animal carcinogens known.

Fusarium molds produce several different mycotoxins, including the trichothecenes, fumonisins, and zearalenone (Richard, 2007). Fumonisins are produced primarily by *Fusarium verticillioides* and several other *Fusarium species* (Richard, 2007), *Fusarium* molds that grow especially well on corn but can also contaminate other grains and soybeans. The effects of fumonisins were first noted in horses where the fumonisins have been implicated in equine leukoencephalomalacia. This fatal neurotoxic syndrome is characterized by extensive necrosis of the white matter in the brain of affected horses (Richard, 2007). Fumonisins are also known rodent carcinogens (Howard *et al.*, 2001). The effects of fumonisins on humans remain unknown, but low-level contamination of grains with fumonisins seems to be fairly common.

Algal Toxins (Phycotoxins)

Marine algae proliferate widely in the ocean and especially in near-shore and reef environments. More than 4000 species of marine phytoplankton are known to exist. It is estimated that 60–80 of these marine algae species are capable of producing phycotoxins (Smayda, 1997). The phycotoxins are ingested by shellfish and fish, and the phycotoxins can be transferred to the edible portions of the seafoods. These marine algae often exist in a dormant state as cysts in the marine sediments. When ideal environmental conditions exist, the algae will bloom creating conditions where the fish or shellfish will become hazardous to ingest. Thus, fish and shellfish may be safe to ingest during certain times and hazardous at other times. The fish and shellfish are only toxic in circumstances where they have the opportunity to feed on toxic marine algae. These algal toxins pass through the food chain from smaller organisms to larger ones. Several acute illnesses are associated with such seafoods, including ciguatera poisoning, paralytic shellfish poisoning, amnesic shellfish poisoning, and tetrodotoxin poisoning (James *et al.*, 2010; Dickey and Plakas, 2010; Taylor, 1988).

Ciguatera Poisoning

Ciguatera poisoning is probably the most common cause of foodborne disease of chemical etiology on a worldwide scale. This foodborne illness is common throughout the Caribbean and much of the Pacific Ocean. However, ciguatera poisoning is now encountered around the world due to the improved distribution of fish (Dickey and Plakas, 2010; Taylor, 1988). In the United States, the illness occurs most frequently in Florida, Hawaii, and the Virgin Islands (Taylor, 1988). Ciguatera poisoning results from the ingestion of fish that have fed on toxic dinoflagellate algae. The toxins involved in ciguatera poisoning are initially acquired by small fish that feed on the poisonous planktonic algae but then pass to larger fishes that feed on the smaller fishes (Taylor, 1988). Several species of dinoflagellate algae appear able to produce toxins of the type associated with ciguatera poisoning; *Gambierdiscus toxicus* is one of the most prominent species (Dickey and Plakas, 2010; Taylor, 1988). Fish that inhabit reef and shore areas in temperate regions, such as grouper, red snapper, barracuda, amberjack, kingfish, Spanish mackerel, mahi-mahi, sea bass, surgeon fish, and eels, are the most commonly implicated species, although many different fish species can likely be involved (Taylor, 1988).

The major toxin involved in ciguatera poisoning is a lipid-soluble, polyether, ionophoric compound with a molecular weight of 1112, known as ciguatoxin (Dickey and Plakas, 2010). However, several toxins have been implicated as well (Dickey and Plakas, 2010). The toxins accumulate principally in the liver and viscera of the fish, but sufficient amounts are found in the muscle tissues to result in ciguatera poisoning among humans ingesting these fish (Taylor, 1988). The toxins are heat stable and thus unaffected by processing or cooking practices (Taylor, 1988).

Ciguatera poisoning can involve variable symptoms that perhaps confirm the role of several different dinoflagellate algae and several different toxins in this syndrome (Taylor, 1988). Gastrointestinal and neurological manifestations predominate (Taylor, 1988; Farstad and Chow, 2001). Gastrointestinal symptoms (nausea, vomiting, diarrhea, and abdominal cramps) predominate in some cases, whereas the neurological symptoms (dysesthesia, paresthesia – especially in the perioral region and extremities – pruritis, vertigo, muscle weakness, malaise, headache, and myalgia) predominate in others (Farstad and Chow, 2001). A peculiar reversal of hot and cold sensations occurs in approximately 65% of all patients (Farstad and Chow, 2001). In severe cases, the neurological manifestations can progress to delirium, pruritis, dyspnea, prostration, brachycardia, and coma (Farstad and Chow, 2001). Many patients do recover within a period of a few days or weeks. However, treatment can be difficult, and some deaths from cardiovascular collapse have been encountered (Taylor, 1988; Farstad and Chow, 2001).

Paralytic Shellfish Poisoning

Paralytic shellfish poisoning occurs with less frequency than ciguatera poisoning but has the potential to be an even more serious illness. Annually on a worldwide scale, an estimated 2000 human cases occur (Van Dolah, 2000). The implicated shellfish become toxic by ingestion of toxic dinoflagellate

algae that belong to three genera: *Alexandrium*, *Gymnodinium*, and *Pyrodinium* (Van Dolah, 2000). Blooms of the toxic dinoflagellates are quite sporadic, so most affected shellfish are hazardous only during the times of the blooms (Taylor, 1988). In most shellfish species, the toxins are cleared from their system within a few weeks after the end of the dinoflagellate bloom (Taylor, 1988). However, a few species, such as the Alaskan butter clam, seem to retain the toxin for long periods (Taylor, 1988). Paralytic shellfish poisoning can involve a range of molluscan shellfish, such as clams, mussels, cockles, and scallops (Taylor, 1988; Van Dolah, 2000). The molluscan shellfish are filter feeders and concentrate the toxins from the dinoflagellate algae as they feed. The causative agents involved in paralytic shellfish poisoning are neurotoxins known as saxitoxins, which act by binding to and blocking the sodium channels in nerve membranes (Shimizu, 1988; Taylor, 1988). Saxitoxins are heat stable, so processing and cooking have no effect on their toxicity (Taylor, 1988).

Saxitoxins are very potent neurotoxins, and the symptoms of paralytic shellfish poisoning are reflective of neurotoxicity with tingling and numbness of the lips, tongue, and fingertips followed by numbness in the legs, arms, and neck; ataxia; giddiness; staggering; drowsiness; and incoherent speech progressing to aphasia, rash, fever, and respiratory and muscular paralysis (Taylor, 1988). Death from respiratory failure occurs with some frequency, usually within 2–12 h depending on the dose ingested (Taylor, 1988). No antidotes exist, but the prognosis is good if the victim survives the first 24 h of the illness (Taylor, 1988).

Amnesic Shellfish Poisoning

Amnesic shellfish poisoning (ASP) is a more recently recognized phycotoxicosis. The first recognized outbreak of ASP occurred in Canada in 1987 from the ingestion of mussels harvested near the shore of Prince Edward Island (Perl *et al.*, 1990). This outbreak involved more than 100 cases and at least 4 deaths (Perl *et al.*, 1990; Teitelbaum *et al.*, 1990). The source of the toxin was a dinoflagellate subsequently identified as *Pseudonitzschia* spp., which was blooming in an isolated area of Prince Edward Island at the time of the outbreak (Jeffery *et al.*, 2004). The toxin was identified as domoic acid, a neuroexcitatory amino acid (Jeffery *et al.*, 2004). ASP is characterized by gastrointestinal symptoms and unusual neurological abnormalities (Perl *et al.*, 1990). The gastrointestinal symptoms (vomiting, abdominal cramps, and diarrhea) occur in the first 24 h after onset of the illness. The neurological symptoms are more severe and ensue within 48 h after onset. These symptoms include severe incapacitating headaches, confusion, loss of short-term memory, and, in a few cases, seizures and coma. Severely affected patients who did not die experienced prolonged neurological sequelae, including memory deficits and motor or sensorimotor neuronopathy or axonopathy (Teitelbaum *et al.*, 1990).

Processing-Induced Toxicants

Potentially toxic substances can form under certain processing conditions, especially heat treatments. As processing treatments prolong the shelf life of foods and guard against microbial hazards, the development of processing-induced toxicants is a classic risk versus benefit puzzle. Several examples of processing-induced toxicants, such as heterocyclic aromatic amines, hydroxymethylfurfural, advanced glycation end products, nitrosamines, and acrylamide, form as a result of food processing and preservation commonly used in the food industry as well as in the home. Processing-induced toxicants tend to raise chronic toxicity concerns. Acute symptoms are not known to occur from this category of foodborne toxicants. Acrylamide formation occurs in foods having high levels of carbohydrates and asparagine residues when heated under certain condition. Acrylamide serves as a good example of processing-induced toxicants.

Acrylamide

Acrylamide (2-propenamide) is colorless and odorless and is used in manufacturing polyacrylamide and acrylamide copolymers employed in the paper and textile industries, as flocculants in wastewater treatment, as soil conditioning agents, and as grouting agents for construction of dam foundations, tunnels, and sewers (Mills *et al.*, 2009; Zhang and Zhang, 2007). In the late 1990s in Sweden, researchers investigating the occurrence of neurotoxic symptoms in railway tunnel makers found high levels of acrylamide hemoglobin adducts in blood samples of the workers. Acrylamide polymer had been used as a sealant in the tunnel and apparently some of this sealant entered a nearby stream, leading to the contamination of the local water. Dead fish and paralyzed cattle were also found in the immediate area and fish and cattle were also found to have higher levels of these adducts (Mills *et al.*, 2009). As the adducts were also found in control samples, the researchers questioned whether cooked foods could be the source of acrylamide exposure in humans. An animal study showed that rats fed fried feed had higher levels of the acrylamide hemoglobin adducts than rats fed a standard diet (Tareke *et al.*, 2000). Subsequently, other researchers detected acrylamide in foods with French fries, potato chips, breakfast cereals, cookies, brewed coffee, breads and toasts, and pies and cakes having among the highest levels (Roach *et al.*, 2003).

Acrylamide forms in foods during heating and as a by-product of the Maillard reaction, which leads to desirable color, flavor, and aroma development in cooked foods. Acrylamide forms due to a reaction between the amino acid, asparagine, and reducing sugars, such as glucose and fructose, under elevated temperatures (above 120 °C) in low moisture conditions. The highest levels of acrylamide are found in fried, baked, and broiled foods (Tareke *et al.*, 2002). Acrylamide does not form in foods that are boiled or microwaved (Tareke *et al.*, 2002). Acrylamide is rapidly absorbed from the gastrointestinal tract, distributed throughout the body, and metabolized to form glycidamide, which is a reactive epoxide thought to be responsible for the genotoxic effects associated with acrylamide exposure (Mills *et al.*, 2009). Acrylamide is neurotoxic and carcinogenic in animal models, which lead the International Agency for Research on Cancer to classify acrylamide as a category 2A carcinogen (probably carcinogenic to humans). Several epidemiological studies have investigated

the association between oral exposure to acrylamide from food sources and the incidence of several types of cancer in humans, but no association has been found (Mills *et al.*, 2009).

Natural Toxicants

Natural constituents of foods from fungi, plants, and occasionally animals may be hazardous under some circumstances of exposure. Of course, some fungi, plants, and animals should not be consumed as food because of their inherent hazards but are accidentally or intentionally consumed on occasion resulting in foodborne illness. Beyond the poisonous species, many other plants and animals contain levels of naturally occurring toxicants that are probably not hazardous to humans except when abnormally large quantities of such foods are ingested. Other naturally occurring toxicants in certain plants are inactivated or removed during processing or preparation of foods before consumption. However, foodborne illness can result from the failure to adhere to such processing and preparation practices.

Poisonous Animals

Few acutely toxic animal species exist with the possible exception of pufferfish, although the toxin in pufferfish is most likely a naturally occurring contaminant. Furthermore, animal tissues and products are not generally hazardous if ingested in abnormally large quantities, at least not on acute basis with the exception of vitamin A (Taylor, 2002; DiPalma and Ritchie, 1977) as previously discussed. Of course, this statement does not take into account the nutritional concerns with cholesterol and saturated fats. Although overconsumption of cholesterol and saturated fat on a chronic basis may be considered as potentially deleterious to health, these substances are not generally regarded as toxicants. Milk can occasionally contain hazardous substances, but these are typically contaminants that are secreted into the milk after the cow has eaten a poisonous plant (Panter and James, 1990). Ovomucoid, an egg white protein, is a trypsin inhibitor, but this activity is diminished by cooking and ovomucoid does not appear to inhibit human trypsin (Feeney *et al.*, 1969). Molluscan shellfish can contain arsenical compounds but typically at levels that are not considered to be especially hazardous (Falio *et al.*, 2006). Additional examples are difficult to find.

Poisonous Plants

In contrast, many poisonous plants exist in nature (Poppenga, 2010). Plants such as water hemlock and nightshade were classically used to poison one's enemies. The risk of ingestion of poisonous plants is rather low as consumers purchasing foods from commercial sources are usually able to avoid their ingestion. However, intoxications can and do occur among individuals who harvest foods in the wild (Huxtable, 1990). For example, foxglove can be mistakenly identified as comfrey, a popular herb for brewing of herbal tea. Foxglove contains digitalis, a potent cardiotoxic substance and serious cardiovascular symptoms can develop when foxglove is ingested (Dickstein and Kunkel, 1980; Lin *et al.*, 2010). The intentional or unintentional ingestion of poisonous plant species such as foxglove (digitalis), *Nicotiana glauca* (anabasine), and jimsonweed (atropine and other tropane alkaloids), to name but a few can even have fatal consequences (Centers for Disease Control and Prevention, 2010; Steenkamp *et al.*, 2002; Steenkamp *et al.*, 2004). Although digitalis and atropine are both useful pharmaceutical agents, their ingestion from natural sources in uncontrolled doses can be fatal.

Plant food products purchased from commercial sources can cause acute intoxications on rare occasions. For example, a commercial herbal tea known as gordolobo yerba sold to the Mexican American population in Arizona was contaminated with *Senecio longilobis*, a well-known poisonous plant (Stillman *et al.*, 1977). The herbal tea was promoted as a cure for colic, viral infections and nasal congestion in infants. Six infants died from ingestion of the contaminated herbal tea, which contained 1.5% of dry weight of pyrrolizidine alkaloids. One of the deceased infants was estimated to have consumed 66 mg of the alkaloids over a 4-day period. *Senecio* plants contain a group of toxicants known as pyrrolizidine alkaloids (Coulombe, 2003). Acute exposures to hazardous doses of pyrrolizidine alkaloids as in the case of the contaminated herbal tea can cause ascites, hepatomegaly, venoocclusive liver disease, abdominal pain, nausea, vomiting, headache, and diarrhea (Stillman *et al.*, 1977). The infants who died experienced liver failure.

Pyrrolizidine alkaloids can also cause chronic symptoms, including liver cancer and cirrhosis, if ingested in smaller quantities over more extended periods of time (Coulombe, 2003). With such chronic, low-level intake, the effects on the liver are cumulative and irreversible. Several pyrrolizidine alkaloids are well-documented carcinogens in laboratory animals. The chronic ingestion of products containing low levels of potentially carcinogenic pyrrolizidine alkaloids presents unknown carcinogenic risks. Several herbal teas commonly contain lower levels of pyrrolizidine alkaloids that are not typically hazardous on an acute basis. For example, comfrey (*Symphytum officinale*) typically contains a total alkaloid level of 0.003–0.02%, including a pyrrolizidine alkaloid symphytine. It is unknown whether chronic intake of comfrey tea would significantly increase the risk of development of liver cancer.

Thousands of other alkaloids with varying degrees of toxicity are known to occur in plants (Koleva *et al.*, 2012; Rietjens *et al.*, 2005). Some, like the pyrrolizidine alkaloids in *Senecio*, are very hazardous, but others are much less hazardous.

Many of the naturally occurring toxicants in plant-derived foods occur at doses that are not acutely toxic at typical levels of consumption, but that can be toxic when large quantities of the food are eaten. Examples include solanine and chaconine in potatoes, oxalates in spinach and rhubarb, furan compounds in mold-damaged sweet potatoes, and cyanogenic glycosides in lima beans, cassava, and many fruit pits (Rietjens *et al.*, 2005). Because there are so many possible examples, the cyanogenic glycosides serve as an illustrative example (Vetter, 2000). Cyanogenic glycosides release cyanide from enzymatic action occurring during the storage and processing of the foods or on contact with stomach acid. Wild varieties of lima beans

contain high and potentially hazardous levels of cyanogenic glycosides, but the commercial lima bean varieties contain minimal amounts of these cyanogenic glycosides. Commercial lima bean varieties have an HCN yield of ≤ 10 mg per 100 g of lima beans (wet weight). As the lethal oral dose of cyanide for humans is 0.5 mg kg^{-1}, a 70 kg adult would have to ingest 35 mg of cyanide, an amount that would require the ingestion of at least 350 g of lima beans. Such high levels of consumption are quite unlikely, so human illnesses from cyanide intoxication have never been reported from ingestion of commercially harvested lima beans. Wild varieties of lima beans contain much higher levels of the cyanogenic glycosides (up to 300 mg HCN per 100 g). Cyanogneic glycosides also occur in other plants. In Africa and South America, cyanide intoxications have occurred from the consumption of abnormally large quantities of cassava (Vetter, 2000; Cliff *et al.*, 2011). Such episodes occur primarily when other foods are in short supply. Acute cyanide intoxication has also occurred from the ingestion of fruit pits (Morse *et al.*, 1976). The symptoms of cyanide intoxication include a rapid onset of peripheral numbness and dizziness, mental confusion, stupor, cyanosis, twitching, convulsions, coma, and death when sufficient doses are consumed (Vetter, 2000).

Some naturally occurring toxicants in plant-based foods are hazardous only when the foods are eaten raw because processing and preparation inactivate or remove the potentially hazardous substances. For example, raw legumes, including soybeans, contain trypsin inhibitors, lectins, amylase inhibitors, saponins, and various antivitamins (Liener, 1994), potential toxicants that are inactivated during the heating and fermentation processes used with legume-based foods. For example, raw kidney beans contain lectins that are typically inactivated during cooking. In cases where kidney beans were eaten in undercooked form, nausea, vomiting, abdominal pain, and bloody diarrhea resulting from the lectins were encountered (Rodhouse *et al.*, 1990).

Poisonous Mushrooms

Mushrooms are often poisonous, so the harvesting of wild mushrooms can be a hazardous practice. Mushroom poisoning incidents occur periodically around the world (Diaz, 2005). Poisonous mushrooms contain a variety of naturally occurring toxicants (Diaz, 2005; Spoerke, 1994).

Amatoxin and phallotoxin are the most hazardous mushroom toxicants. Amatoxin is characteristically produced by *Amanita phalloides*, the death cap mushroom. Acute amatoxin intoxication occurs in three stages. The first stage begins to develop 6–24 h after ingestion of the mushrooms and is characterized by abdominal pain, nausea, vomiting, diarrhea, and hyperglycemia. The second stage is a short period of remission that follows. In the third and often fatal stage, severe liver and kidney dysfunction leads to hypoglycemia, convulsions, coma, and death. Death resulting from hypoglycemic shock occurs 4–7 days after the onset of symptoms.

Hydrazines are another group of mushroom toxins. Gyromitrin, a hydrazine produced by *Gyromitra esculenta* or false morel mushrooms, causes acute symptoms, including a bloated feeling, nausea, vomiting, watery or bloody diarrhea, abdominal pain, muscle cramps, faintness, and ataxia occurring with a 6–12 h onset time.

Fly agaric (*Amanita muscarina*) produces muscarine, a neurotoxic substance that affects the autonomic nervous system. Symptoms appear rapidly after ingestion of fly agaric and include perspiration, salivation, lacrimation with blurred vision, abdominal cramps, watery diarrhea, constriction of the pupils, hypotension, and a slowed pulse.

Ibotenic acid and muscimol are hallucinogenic, ostensibly exerting their actions on the central nervous system. These toxins cause dizziness, drowsiness followed by hyperkinetic activity, confusion, delerium, incoordination, staggering, muscular spasms, partial amnesia, a coma-like sleep, and hallucinations beginning 30 min to 2 h after ingestion. Fly agaric is also a good source of ibotenic acid and muscimol.

Psilocybin and psilocin are also hallucinogenic substances found in Mexican mushrooms, *Psilocybe mexicana*. The symptoms associated with Mexican mushroom toxins include pleasant or aggressive mood, anxiety, unmotivated laughter and hilarity, compulsive movements, muscle weakness, drowsiness, hallucinations, and sleep beginning within 30–60 min after ingestion of the mushrooms. Recovery is often spontaneous in 5–10 h. However, when the dose of psilocybin and psilocin are sufficiently high, prolonged and severe sequelae, even death, can occur.

Coprine is a mushroom toxin that causes symptoms only when ingested with alcoholic beverages. Coprine is produced by *Coprinus atramentarius*. Symptoms begin within 30 min of ingestion of the mushrooms but only if alcoholic beverages are also consumed simultaneously and include flushing of the neck and face, distension of the veins in the neck, swelling and tingling of the hands, metallic taste, tachycardia, and hypotension progressing to nausea and vomiting. Symptoms persist for up to 5 days.

Glossary

Browse Edible plant parts (leaves, bark, and stems) of woody species consumed by grazing animals.
Forage and Herbage Any herbaceous plant that is consumed by livestock.
Greenchop Forage chopped and fed fresh to livestock.
Hay Dried forage, typically baled and stored.
Pasture Cultivated crops grazed by livestock.
Rangeland and grazingland Uncultivated areas grazed by livestock.
Roughage General term incorporating all forages, straws, and fibrous materials such as jute.
Silage Forage that is anaerobically fermented and preserved.
Stover Leafy or stalky material of grain-producing plants used as a forage (e.g., corn stover).
Straw Dried stem material remaining after harvest of a grain crop (e.g., wheat and rice straw).

Introduction

Forages are among the most important crops to mankind, even though harvested fruit, vegetable, grain, and oilseed crops are more widely recognized by urban cultures. Forages make possible the harvesting of solar radiation for the benefit of human nutrition by plants that are then converted into foodstuffs by ruminants and nonruminants, forming one of the oldest food-production systems in human history. Forages are often grown at sites and under conditions where it is not possible to cultivate other crops. Forages have an ancient history but remain vital today.

Forage production systems are highly diverse and directly linked to animal agriculture. Formally, forages include rangeland (forested and nonforested), pastureland (managed and nonmanaged, seasonal, and intensively grazed), harvested forage crops including dried products (hay), fermented forages (silages), and fresh-fed harvested forages (greenchop). They include a wide range of species, including cool- and warm-season grasses; legumes such as alfalfa and clovers; forbs; and grain crops, such as corn, sorghum, soybean, and small grains (oats, wheat, barley, and triticale) that are harvested as forages.

Forage crops, the focus of this article, are differentiated from naturally occurring rangeland and pasture by the degree of human intervention and management. Forages, by definition, generally only have economic value through animal products. In partnership with animal enterprises, forages produce many of the staple foods important to mankind: meats, milk, and fibers, such as wool. Closely related to forage crops are cellulose-producing plants, such as switchgrass, grass straws, and stovers, that produce fibers which can be used for cellulosic biofuels, erosion control, feeds, and animal bedding. Forage crops are sometimes perceived as a lower value component of agriculture but often are among the top revenue-producing components of a region's agricultural output through the production of valuable animal products.

Not insignificantly, forage crops, pastures, and rangeland systems also contribute important environmental services (Wedin and Russelle, 2007; Franzluebbers, 2013; Karlen *et al.*, 2007; Putnam *et al.*, 2001). These include contributions such as protection of soil, air, and water quality, sequestration of soil carbon, cycling of nutrients, absorption of excess nitrate from contaminated water, suppression of weeds, and provision of important wildlife habitat (**Figure 1**).

As high-quality cropland diminishes in relationship to expanding human populations in the twenty-first century, the dual roles of forage crops for both food production and provision of environmental services may be important to the future of agricultural systems. The purpose of this article is to provide a broad background on the role and biology of forage crops in agricultural systems, with an emphasis on harvested forage crops and the principles of forage crop production.

History

> and the earth brought forth grass, and herb yielding seed after its kind… and God saw that it was good
>
> –Genesis, 1–12

Forage crops do not have a complete historical archeological record, due to the difficulty of preserving herbaceous plants compared with seed-bearing crop plants, but it is clear that forages were a key primary producer in early human cultures and were the basis of early agriculture (Barnes and Baylor, 1995; Barnes and Nelson, 2003). Although formal animal domestication did not occur until later, forages were the key basis for food production for hunter-gatherer societies for the vast majority of the history of *Homo sapiens*, with coordinated animal harvests leading to semidomestication (Harlan, 1975; Diamond, 2002). The major grasslands of the world, such as the prairies of North America, the pampas of South America, the steppes of Central Asia, and the velds of Africa, form the historical biological basis for forage systems (Williams, 1980). Forages codeveloped with grazing animals and human societies during periods reaching into antiquity. The formal domestication of goats, sheep, and then cattle can be traced to earlier

Figure 1 Deer in a Washington State alfalfa field. Forage crops are a major component of land use in the United States and provide a range of axillary environmental services, such as wildlife habitat (Photo: Sharla Wagoner).

than 10 000 to 9500 BCE and now to probably 12 000 BCE (Zeder, 2008). Thus, range and forage grasses, legumes, browse, and forbes provided the basis for human nutrition throughout much of the history of civilized man.

However, these historical forage crops were largely made up of native, noncultivated range and short-term seasonal pastureland, as animals were moved from place to place. In terms of true 'farming' (controlled animal production), animal domestication may have proceeded plant domestication by many years, or at least evolved simultaneously. Semicultivated agricultural techniques (via burning, weeding, seeding, or other techniques) were likely to have occurred later and simultaneous with settled cultures of the fertile crescent (Zeder, 2008).

The Need for Conserved Feed

> The most important invention of the last two thousand years was hay. …
>
> –Freeman Dyson, 1999, Institute for Advanced Study, Princeton University

Some might question Dyson's hyperbole that forages were the most important development in 2000 years, but his logic is as follows:

> Without grass in winter you could not have horses, and without horses you could not have urban civilization. Sometime during the so-called dark ages, some unknown genius invented hay, forests were turned into meadows, hay was reaped and stored, and civilization moved north over the Alps. So hay gave birth to Vienna and Paris and London and Berlin, and later to Moscow and New York.
>
> –Dyson, 1999

Dyson may be onto something; there is little doubt that conserved forages were a key technical requirement for settled, stable animal agriculture and therefore towns and cities. Seasonally determined 'booms and busts' of forage availability were (and are) the norm in most grazing grassland systems due to seasonal rainfall patterns or winter cold. Thus, the conservation of forages through drying (hay) and fermentation (silage) were important historical advances to stabilize and sustain agriculture and settled communities. Although movement of livestock for seasonal pasture is still widely practiced, the emergence of forages as managed crops created a reliable local supply of feed without moving livestock long distances for seasonal pastures.

Harvested forages as hay and silage have been components of diversified farms in Europe and Asia from the earliest settled farmsteads. In Great Britain, the scythe and the process of haymaking date from 750 BCE (Barnes and Baylor, 1995), belying Dyson's 2000-year time frame, and references to proper curing were described by the Roman writer Columella in AD 50 (Barnes and Nelson, 2003). Red clover (*Trifolium repens*) was cultivated in Southern Europe in the third and fourth centuries AD (Evans, 1976) and was brought to America by early settlers (Gibson and Cope, 1985). As pre-Columbian America lacked significant large domestic grazing animals (cows, sheep, goats, and horses), there is little evidence for harvested forages before European settlement, although the contributions of early Native American farmers to the world's food crop larder is well known (e.g., maize, beans, tomato, and potato). Significant management of grasslands and forested farming systems through burning by Native Americans to increase game populations was common.

Some of the earliest development of forages as crops that were seeded and managed are likely traced to alfalfa (*Medicago sativa* L.) and selected cool-season grasses in the Mediterranean and near Asian agricultural regions. Sometimes very important forage species were carried intentionally or unintentionally by immigrants to their new homes. Bermudagrass (*Cynodon dactylon*), a very important forage in the Southern United States, was apparently brought to the United States inadvertently by African slave ships from its center of origin in Africa. It was stuffed into mattresses as bedding and eventually some of the seed ended up in places where it grew successfully. Kentucky bluegrass (*Poa pratensis*), well-known pasture grass in North America, was apparently introduced to America from England as part of the sweepings of cattle boats.

Alfalfa (*Medicago sativa*), the most important leguminous forage in the United States, is the oldest crop plant which has a name (Russelle, 2001). It originated in the area of modern-day Iran and Turkey and was moved by early Mediterranean civilizations throughout the region and into Europe and Central Asia (Lesins, 1976). The horse was a key factor in its early domestication, as it was transported by nomadic peoples and by early Assyrian and Babylon empires from the seventh century BC (Michaud *et al.*, 1988). Pliny and Strabo, early Roman writers, recorded that alfalfa was introduced into Greece as early as 490 BC by invading Medes and Persians. Alfalfa was often associated with the military might of the Greek, Roman, Persian, and later the Islamic empires through its role in feeding war horses (Lesins, 1976). Alfalfa was introduced into China in the second century CE along with Arabian horses (Russelle, 2001) and into the new world by Spanish colonialists.

The first recorded attempt to grow alfalfa in the United States was in Georgia in 1736, and it was grown by both George Washington and Thomas Jefferson in the 1790s, but it was really only successful after its California introduction

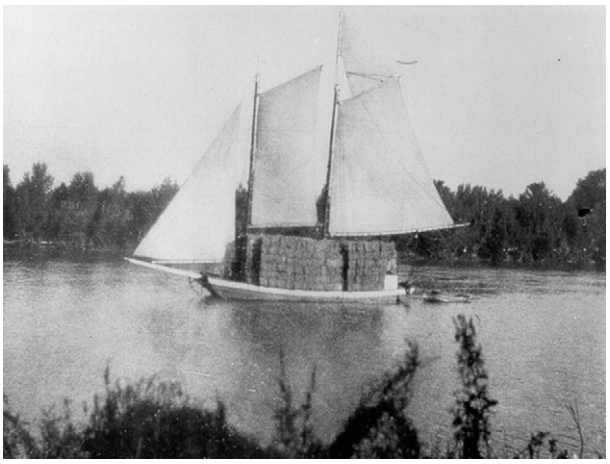

Figure 2 Alfalfa hay was commonly transported by sailing scows in the Sacramento/San Joaquin delta to dairies around San Francisco, c. 1890s. Alfalfa was first introduced in the 1700s in eastern states but was first successful in the United States after California's Gold Rush in the 1850s and quickly moved to eastern states to become the most important hay crop in the United States.

Table 1 Crop values of the top US crops and the value of dairy and beef industries in the United States, 2010–2012

Crop	*2010*	*2011*	*2012*	*Crop rank-US*
	Billions of dollars			
Corn grain	64.6	76.9	77.4	1
Cattle and calves	53.0	65.3	69.6	
Soybean grain	37.5	38.5	43.2	2
Milk and cream	31.3	39.5	37.0	
Hay (all)	14.7	18.2	18.6	3
Hay (alfalfa)	7.7	10.9	10.4	(4)
Wheat (all)	12.8	14.3	17.9	4 (3)
Cotton (all)	7.3	6.9	6.0	5
Potatoes	3.7	4.0	3.9	6
Rice	3.1	2.7	3.0	7
Sugarbeets	2.1	2.0	2.0	8
Sorghum grain	1.6	1.3	1.6	9
All field crops	157.5	175.4	187.8	
All fruit nut crops	21.2	24.2	25.8	

Note: Alfalfa is listed as a subcomponent of all hay. Values in parentheses show the relative ranking of alfalfa and wheat if alfalfa was considered a separate crop rather than a subset of all hay.

around 1850 as 'Chilean clover.' Subsequently, alfalfa moved eastward to Utah and other states in the expanding West and later to the colder, wetter climates of the East. The introduction of 'Grimm' cultivar from Germany into Minnesota in 1857 made possible the development of cold-hardy varieties, the descendants of which are grown today in many cold northern regions. Alfalfa and other hays have been transported to dairy and livestock producers for considerable distances in western US states for more than 100 years (Figure 2).

The breeding and production of improved forage crops is a relatively recent phenomenon, occurring mostly during the twentieth century after some early introductions in the 1800s (Michaud *et al.*, 1988). A wide range of improved forages have become available during the latter half of the twentieth century, led by alfalfa; (there are more than 250 cultivars of alfalfa available in North America alone (NAFA, 2014)). However, it is also accurate that the genetic advancements with forage crops have not been as dramatic as with the major grain crops, due in part to the relatively miniscule investment of public or private resources in their improvement in comparison with corn, wheat, soybean, and vegetable crops.

Importance of Forages

By definition, 'forage' is any herbaceous plant species or plant part that is directly consumed by livestock (Barnes *et al.*, 2007). Generally, entire plant parts are consumed, differentiating forages from 'grain' (such as corn, barley, or wheat grain) or by-products such as oilseed meals, which are also major livestock feeds (see Glossary).

Current figures estimate that 26% of the world's land area and 70% of the world agricultural area is covered by grasslands, directly contributing to the livelihoods of more than 800 million people (FAO, 2008). Others have estimated the world's grazing and grasslands, defined as land dominated by grasses, to occupy 52.5% of the world's terrestrial land area (excluding Greenland and Antarctica), making it one of the most important ecosystems worldwide (Reynolds, 2005). However, much of these lands include nonmanaged or partially managed mixed grasses, legumes, and forbs. There are additional millions of hectares of pasture, hay, and silage crops which occupy highly-managed farmland. Typically, world acreage and value of forage crops are not compiled in a complete fashion that includes all forages or even all forage crops, and detailed data are frequently lacking.

In the United States, 'hay' is ranked as the third most important crop in economic value behind only corn and soybean (Table 1). This does not include pasture, rangeland, or silage crops but includes both grassy and leguminous forages harvested as hay. The primary species contributing to the US$14–18 billion year^{-1} hay crop in the United States are alfalfa (*Medicago sativa*), tall fescue (festuca arundinacea), bermudagrass (*Cynodon dactylon*), ryegrass (*Lolium* spp.), orchardgrass (*Dactylis glomerata)*, bromegrass (*Bromus* spp.), timothy (*Phleum pretense*), and various clovers, prominently red clover (*Trifolium pretense*) and white clover (*Trifolum repens*). Alfalfa is the most important hay in the United States and would be ranked fourth in economic value (behind corn, soy, and wheat), if considered by itself (Table 1).

Approximately 870 000 US farms produce hay crops, according to the 2007 USDA Agricultural Census, occupying >65 million acres of farmland (Figure 3). Virtually every agricultural state produces hay crops, with the largest production occurring in the midwestern and western states. Alfalfa production (a subset of hay production), predominately occurs in major dairy and beef-producing states in the west and midwest: the top ranked states are California, South Dakota, Idaho, Montana, Nebraska, Wisconsin, Iowa, North Dakota, Kansas, and Minnesota (USDA-NASS data). Approximately

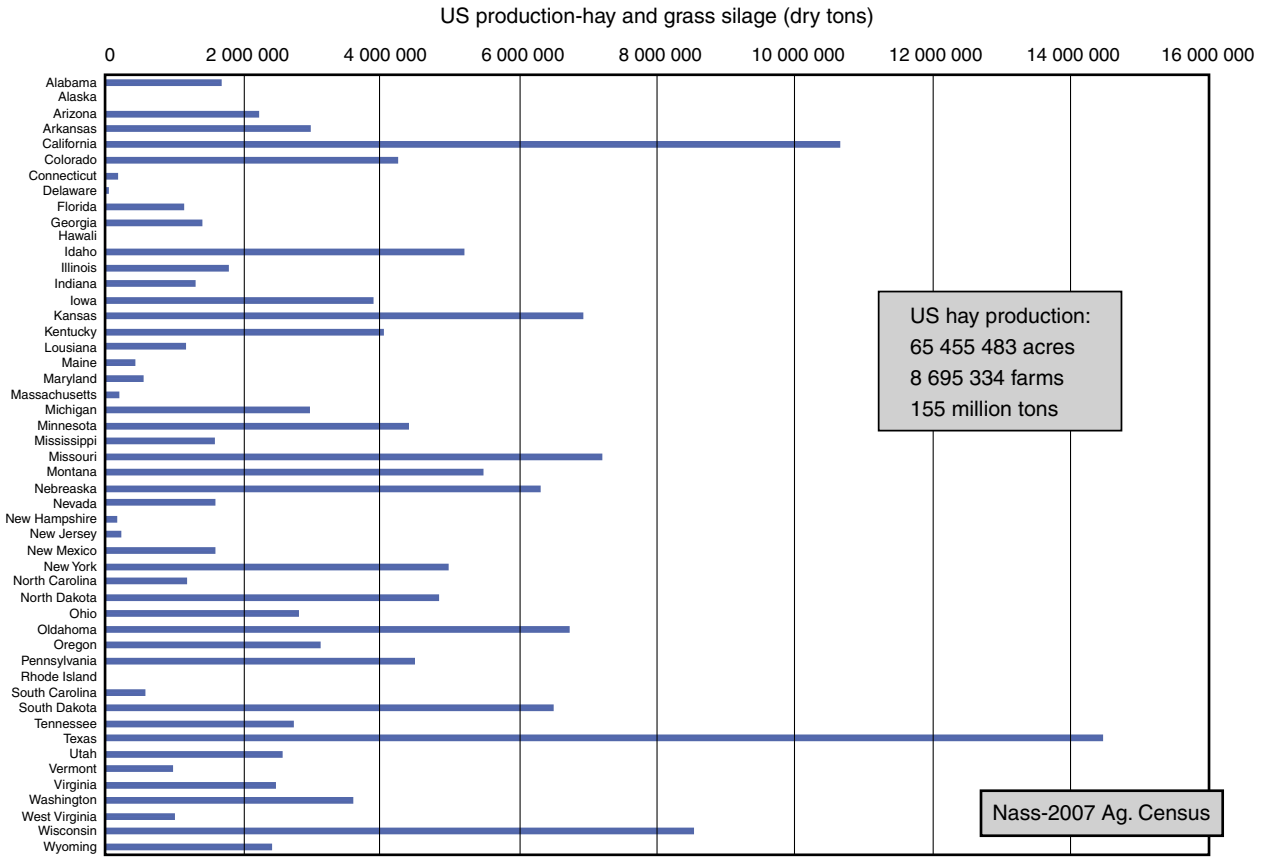

Figure 3 US production of cultivated hay, grass silage, alfalfa haylage, and greenchop (2007). This does not include corn or sorghum (or other) silages, grazed farm pasture, grazed forested lands, or rangeland. Reproduced from USDA-NASS. Available at: http://www.nass.usda.gov/ (accessed 09.01.14).

50% of the US alfalfa is produced in midwestern states, 42% from western states (mostly irrigated), and 8% from eastern states.

Although hay is of economic importance in its own right, forages have economic value primarily through ruminant livestock products. Thus, the value of cattle and calves and the dairy industry, which could not exist without forage crops, is inextricably linked to the value of forages. Dairy and beef are among the top four economic agricultural products in the United States (Table 1). Beef cattle are highly dependent on grazing systems, utilizing seasonal pasture as well as hay and silage crops (primarily during the winter months). Dairy cows are more dependent on stored hay and silage forage crops.

Nationwide, the majority of forages are utilized on-farm, rather than being sold, although there are large east–west differences in this respect. In most western states a vast majority of the alfalfa hay is marketed (sold between farms), whereas this is reversed in eastern and midwestern states, where most of the forage is used on the farm in which it is grown. In both cases, some portion of the economic value of dairy and beef must be attributed to the forage crops that support those industries. For example, in 2011, the value of the sale of hay in California was US$1.7 billion, whereas the value of dairy was US$7.6 billion and cattle and calves US$2.8 billion, with dairy the most important agricultural product in the state (CDFA, 2013). Accounting for 'hay' in these summaries does not include the value of pasture, silage, or greenchop. Forages and livestock are interdependent industries, and this example illustrates how the economic value of forages is frequently underestimated.

Forage Agroecosystems

Forages grown on grazing lands, range, and grazed forestry lands consist of greater than one-third of the total land use in the United States (including cities, water bodies, deserts, agriculture, and other land uses, Table 2). Grazing land use has declined from approximately 50% of land use in 1945, a reduction that is primarily due to a reduction in grazed forested regions. However, forage, grazing, and grasslands remain an important, if not dominant land use, exceeding that of crop production agriculture in its entirety (Nickerson *et al.*, 2011). This estimation does not include harvested hay and silage crops (as per Table 1), which would add approximately 65 million acres to the 'total forages' tally, but reflects pasture, grassland, and grazed areas within forested regions. The importance of animal–forage systems as a primary if not dominant agroecosystem land use in the United States may be a surprise to many.

Table 2 Land use (acres) in United States, 1945–2007

Land use	*1945*	*1974*	*2007*
	(× 1000 acres)		
Cropland (including harvested forages)	450 693	465 084	408 139
Cropland used as pasture	47 448	82 736	35 989
Grassland pasture and range	659 498	597 833	613 733
Forest land grazed	345 000	179 419	127 130
Total US land	2 274 944	2 263 587	2 263 962
Percent used for grazing/pasture	46%	38%	34%

Note: Total land use includes water bodies, cities, agricultural uses, and roads/canals. Cropland includes all harvested hay and silage crops, grain crops, oilseeds, sugar and fiber crops, orchard, and vegetable crops. Cropland used as pasture is cropland in semipermanent pasture, whereas grassland and pasture includes all nonforested grazing areas. Percentage used for grazing does not include hay, silage, and greenchop forage that are included in cropland.

Forage crops can be visualized as key components of a 'food-producing biological system' involving soil, water, climate, plant communities, animal production, and animal-based food and fiber products (**Figure 4**). Energy, minerals, nutrients, carbon, nitrogen, and other minerals are transformed from the abiotic environment (soil, water, air, and sun) through plant and animal production systems, to food products, such as meat and milk, driven by market demand (West and Waller, 2007). Nutrients can also be recycled back to forage crops in the form of manure, municipal waste, and gasses, such as CO_2 from animal respiration. Nitrogen is of special interest because it is in such short supply in the earth's crust for plant growth and a source of contamination in surface and groundwater (Wedin and Russelle, 2007). Extensive systems (grazing and rangeland) are more important for sheep and beef, whereas intensive cultivated forages are more important for dairy animals and horses, but there is considerable crossover. Complex interactions with human input and environmental influences, such as petroleum and fertilizer inputs, management practices, wildlife habitat, climate and seasonal changes, and powerful market forces, influence this system in many ways (**Figure 4**).

Animal production systems are frequently interrelated across species. For example, milk production based on harvested forage systems (primarily alfalfa, corn silage, and grass hays) also influence beef systems through culled dairy cows and bull calves (Putnam and DelCurto, 2007). The primary animals of worldwide importance that are dependent on forages are beef cows, dairy cows, sheep, goats, and horses (**Figure 4**). Chicken and swine are not generally important for forages; an exception is in major poultry production areas, such as Arkansas and Alabama. Poultry wastes are routinely recycled through grassy beef pastures and the same thing happens in swine production regions (West and Waller, 2007). It should be pointed out that most animal production systems in modern times are highly dependent not only on forage crops but also on grain and by-products from grain or seed-producing crops, particularly corn grain, soybean, and other oilseed meals, and by-products, such as fermentation by-products, cottonseed, citrus and sugar beet pulp, etc. Not generally noticed is the service that animal production systems provide in consuming waste products and by-products that would otherwise have no value and end up in landfills.

Modern Concentrated Animal Feeding Operations (CAFOs) provide major challenges to the cycling of nutrients through forage and grain crops in plant–animal production systems. CAFOs are defined by the EPA as either medium (200–699 for dairy and 30–999 for beef) or large (>700 for dairy and >1000 for beef cows) sized. CAFOs have come to dominate animal production systems in many regions worldwide. For example, in California the size of the average dairy is more than 800 mature milking cows, and many of the beef feedlots in Missouri, Oklahoma, and Texas have tens of thousands of cattle concentrated in single units. This trend of increasing operation size is driven primarily by efficiency and cost considerations and the relatively low profitability margins of animal feeding systems. Major challenges of CAFOs include the concentration of nutrients (predominantly N and P), concentration of salts, and the difficulty of cycling nutrients back through forage systems. Compared with traditional, smaller-scale grazing and feeding systems, CAFOs typically have greater environmental challenges associated with the accumulation of excess salts and nutrients imported to small areas from cropland and air quality impacts from animals, manures, and silage.

Classes of Forage Crops

Although ruminants and nonruminants can ingest many types of herbaceous plants, the most important forage crops consist of herbaceous leguminous plants and cool- and warm-season grasses. Perennials and annuals are both widely used, but perennials are more prevalent. The ascendency of various forage species in different regions is dependent on soil type, climate, and adaptation as well as the necessity for high forage quality. The latter factor, in turn, determines the class of animal that can be economically fed. Frequently, the ability or inability to produce certain types of forage crops due to limitations of soil, water, or climate will determine the class of animal that can be raised in a region. Sheep, goats, beef cows, horses, and dairy cows each have different nutrient requirements, with milk-producing animals having the highest quality requirements. Thus, one finds sheep and goat grazing systems more predominantly in regions with extensive rangelands with more coarse forage species and dairy bovine production in regions capable of producing higher quality hay and silage crops.

Conversely, farmers do not always choose to grow the highest yielding forage crop (production per unit area), due to the need to produce quality forage products (nutrients per unit forage) to optimize milk production or daily weight gain. Thus, a farmer may elect to produce alfalfa, ryegrass, or clover compared with higher yielding forages, such as sudangrass, because the former crops are known to improve milk production or growth. However, most animal production systems have uses for all types of forages, from higher quality forage crops to coarser hays, including silage, crop residues, and roughages. Thus, different types of forages are fed to different classes of livestock according to their dietary needs, from

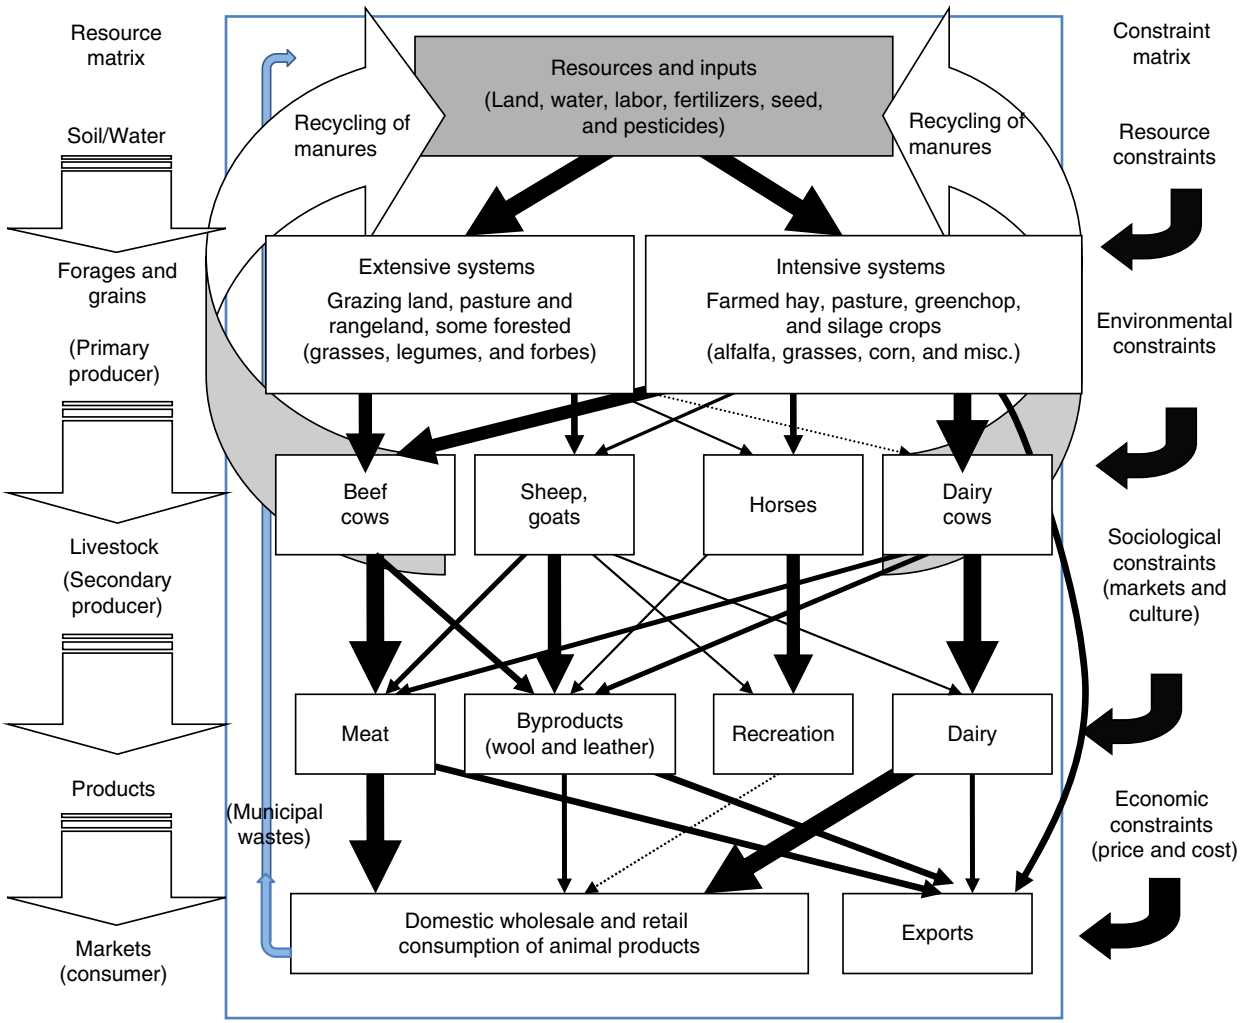

Figure 4 A model of forage food-producing systems consists of the conversion of land and water, through forage crops and grains, with human and other inputs to produce food products under varying constraints. Thickness of arrows indicates importance of flow. Constrains include resource (water and soil), environmental (temperature and environmental impacts), and sociological and economic constraints. Adapted from Putnam, D.H., DelCurto, T., 2007.

high-producing milk cows to heifers and dry cows, horses, beef cows, sheep, and goats.

Here the most important forage crops are discussed, but a wide range of forages can be grown and are important in localized areas, and described in Table 3.

Forage Legumes

There are a wide range of legumes grown as forage crops, both annual and perennial, including alfalfa (*Medicago sativa* L.), various clovers and herbaceous legumes, and seed-bearing crops, such as soybean (*Glycine max*) and cowpea (*Vigna unguiculata*). Forage legumes tend to be higher in protein concentration than grasses and have the advantage of biological N_2 fixation through symbiosis with various *Rhizobia* species, enabling the leguminous forages to be grown without N fertilizers. Worldwide, biological N_2 fixation contributes an estimated 140 million MT of N annually with 85% in agricultural systems coming from pulse and forage legumes (Vance *et al.*, 1988). Forage legumes are frequently highly desired components of forages systems due to the dual benefits of biological N_2 fixation and superior palatability and quality of the forage.

Alfalfa

Alfalfa (*Medicago sativa* L.) or lucerne is the most important forage legume worldwide and frequently called the 'Queen of forages' due to its wide adaptation, high yield, and high quality. This moniker also is due to the fact that it is frequently the most important forage in many regions and is the highest value hay crop in the United States. It is grown from the frozen plains of Southern Canada and Eastern China to the mild climates of Chile's Central Valley to the searing deserts of Mexico and North and South Africa. It is grown as a highly managed cash crop in irrigated regions, such as California

Table 3 Characteristics of many crops commonly grown as forages

Species	*Scientific name*	*Type*	*Life habit*	*Primary use*	*Distinguishing characteristics*
Alfalfa	*Medicago sativa* L.	Legume	Perennial	Principle hay crop in the United States, silage, pasture	Considered the premier forage for dairy production and is the most widely grown hay crop. Called 'Queen of forages' due to high yield and quality
Alsike clover	*Trifolium hybridum* L.	Legume	Short-lived perennial	Pasture	Best adapted to cool climates and tolerates a wide range of soil pH (both acidic and alkaline conditions), poor soil drainage and low fertility
Arrowleaf clover	*Trifolium vesiculosum* Savi	Winter legume	Annual	Hay and pasture	Not tolerant of poor drainage or low fertility. Low bloat potential and naturally reseeds if allowed to mature
Bahiagrass	*Paspalum notatum* Flugge	Warm-season grass	Perennial	Pasture	Subtropical humid grass, well adapted to sandy soils and tolerant of drought, low fertility, close grazing, and continuous stocking. Deep and extensive root system. Little hay potential because of prostrate growth habit
Bermudagrass	*Cynodon dactylon* (L.) pers.	Warm-season grass	Sod-forming perennial	Pasture and hay	Adapted to warm climates but very frost sensitive. Spreads by rhizomes and solons. Propagated by seed and cuttings. Tolerates close grazing
Big Bluestem	*Andropogon gerardii* Vitman	Warm-season grass	Perennial	Primarily summer pasture or hay crop	Native tall grass prairie species well adapted to the Central US. Very cold and drought tolerant. Requires high grazing or cutting height (>6 in.). Used extensively for conservation and wildlife habitat
Birdsfoot Trefoil	*Lotus corniculatus* (L)	Legume	Short-lived perennial	Pasture with some hay	Winter hardy and bloat resistant due to tannin content. Maintains quality after flowering
Brassicas	*Bassica* spp.	Cool-season forb	Annual and biennial	Summer and fall forage for grazing	Includes kale (*B. oleracea* (L), rape (*B. oleracea*), and turnip (*B. rapa* (L). Used primarily as short-season supplemental pasture. Does not tolerate wet soils. High forage quality but may contain toxic compounds if not grazed at the appropriate time. May cause bloat
Bromegrass	*Bromus* spp.	Cool-season grass	Perennial	Pasture with some hay	Primary species include smooth brome, meadow brome, mountain brome, and matua grass. Adapted to well-drained soils. Very winter hardy but does not tolerate flooding. Becomes dormant when stressed for moisture. Can be grazed continuously
Corn	*Zea mays* (L)	Warm-season grasss	Annual	Principle silage crop in the United States	Widely adapted to fertile well-drained soils. High yield and energy content. Stovers can be baled or grazed. High grain component makes for a highly digestible forage. Important for dairies and feedlots as a silage, but stover can be grazed

(*Continued*)

Table 3 Continued

Species	*Scientific name*	*Type*	*Life habit*	*Primary use*	*Distinguishing characteristics*
Crimson clover	*Trifolium incarnatum* L.	Legume	Annual	Pasture, hay, and covercrop	Grown in southern states and the coastal plain. Brilliant red inflorescence
Dallisgrass	*Paspalum dilatutum* Poir	Warm-season grass	Perennial	Pasture	Will tolerate periods of drought, close grazing, and continuous stocking
Elephantgrass	*Pennisetum purpureum* Schumacher	Warm-season grass	Perennial	Pasture	Very tall and high yielding. Adapted to humid tropical and subtropical regions. Extensive root system. Not tolerant of frost or waterlogged conditions
Fescue (tall fescue and meadow fescue)	*Festuca arundinacea* Schreb. *Festuca pratensis*	Cool-season grass	Perennial	Pasture and hay	Predominant forage grass in the United States and widely used for beef cattle production. Very persistent and high yielding. Can be stockpiled in the fall for winter use. Some varieties contain endophytes that improve persistence but produce alkaloids that are toxic to livestock
Kentucky bluegrass	*Poa pratensis* L.	Cool-season grass	Perennial	Pasture	Tolerates flooding and cold conditions. Adapted to northern and temperate regions. Forms extensive sod by rhizomes. Less productive than other taller grasses and rarely seeded alone
Kura clover	*Trifolium ambiguum* Bieb.	Legume	Perennial	Pasture	Persistent winter hardy drought tolerant legume. Spreads by rhizomes. Tolerates close grazing and continuous stocking. Difficult to establish
Lespedeza	*Lespedeza cuneata*	Warm-season legume	Perennial	Used for summer pasture or hay	Low winter hardiness but tolerant of drought, poor drainage, low fertility, and acidity
Medics	*Medicago* spp.	Legume	Annual and perennial	Pasture and cover crop	Prostrate growth pattern, tolerates grazing, reseeds itself
Orchardgrass	*Dactylis glomerata* L.	Cool-season grass	Perennial	Pasture and Hay	Moderate winter hardiness. Relatively easy to establish. Widely used as hay for horses and in pastures. Very shade tolerant
Perennial Peanut	*Arachis glabrata* Benth	Warm-season legume	Perennial	Hay, pasture, and conservation	Grown in subtropical areas. Low cold tolerance. Established with cuttings. Creeping growth habit
Ryegrass	*Lolium perenne* L. and *Lolium multiflorum* Lam.	Cool-season grass	Perennial and annual	Hay and pasture	Highest quality forage grass. Widely used for lactating livestock and for beef prduction. Some perennial varieties contain a fungus that produce alkaloids that can cause disorders in livestock
Reed canarygrass	*Phalaris arundinacea* L.	Cool-season grass	Perennial	Pasture and hay	Very winter hardy and highly adapted to waterlogged conditions. Forms an extensive sod by rhizomes. Difficult to establish but vigorous once established. Some varieties have high levels of alkaloids that reduce palatability and cause health issues

Red clover	*Trifolium pretense* L.	Cool-season legume	Short-lived perennial	Hay and pasture	Widely adapted. Low drought resistance but tolerant of shade and poor drainage. Upright growth habit makes it suitable for hay and pasture
Small grains (oats, barley, wheat, triticale)	*Avena sativa* L., *Hordeum vulgare* L., *Triticum aestivum* L. × *Triticosecale*	Cool-season grasses	Annual	Hay, silage, and occasionally grazing	Used widely as grain crops but can be grown for hay, silage, grazing or greenchop. Small grain forages require moderate to high soil fertility. Very productive under cool conditions and easy to establish. Late harvests include grain component
Sorghum/Sudangrass	Sorghum bicolor L., Sorghum × drummondi	Warm-season grass	Annual	Silage, hay, and grazing	Many cultivars are available, from seed-producing to high-yielding forage types. Sudangrass is a true hay crop whereas most sorghums are silage or grazing types. Adapted to a wide range of soils. More tolerant to low moisture, drought and low soil fertility than corn. Plant during warm periods in spring. Contains prussic acid and may accumulate nitrates which are harmful to livestock at high concentrations
Sweet clover	*Melilotus* spp.	Legume	Biennial	Grazing, hay, or silage	Adapted throughout the United States. Tall legume that reseeds itself. Exceptionally winter hardy and very drought tolerant. Excellent nitrogen fixer. Does not tolerate close grazing. Can cause bloat and contains coumarin, which reduces palatability. Moldy sweet clover should never be fed due to conversion to toxic compounds
Switchgrass	*Panicum virgatum* L.	Warm-season grass	Perennial	Grown as a summer forage for pasture and hay	Native to North America. Good tolerance to drought and heat. Good winter hardiness. Also used as a biofuel
Timothy	*Phleum pretense* (L)	Cool-season grass	Perennial	Hay and some grazing	Produces a storage structure called a haplocorm. Highly valued as a hay for horses. Does not tolerate close grazing or continuous stocking. Very winter hardy
White clover	Trifolium repens (L)	Cool-season legume	Perennial	Used mostly for permanent pasture	Includes Dutch and Ladino types that are larger and more productive than wild types. Low tolerance to heat and drought but tolerates flooding and acid soil conditions. Spreads by stolons. Well adapted for grazing but has high bloat potential
Wheatgrass	Various	Cool-season grasses	Perennials	Grazed or hayed	Various wheatgrass species are adapted to western and northern US. Important range grass for grazing, hay and soil conservation. Most popular species include Western, Intermediate, Crested, Pubescent, and Tall Wheatgrass

Figure 5 Alfalfa production field in Northern California, showing Mt. Shasta in the background (Photo: Steve Orloff).

(Figure 5) but also as a pasture crop for horses and cattle in midsouthern states, and millions of hectares are grown in Argentina in grazing dairy, beef, and sheep operations. Alfalfa is often the most desired forage for dairy production – it is no accident that the primary alfalfa production regions in the United States correspond with areas of high alfalfa acreage, such as Wisconsin, California, and Idaho.

Alfalfa is widely recognized as the oldest forage plant (Michaud *et al.*, 1988) and remains a dominant and highly desired forage in modern times. It originated in Asia Minor, Iran, and the dry highlands of Turkmenistan, regions of hot, dry summers and well-drained soils, which is why it has been highly successful in similar environments in modern times. It was, for many centuries, associated with horses and military might of Indo-European empires from at least 700 BC (Lesins, 1976), and the very word 'alfalfa' has Arabic and Persian roots and connotes 'best horse fodder' (Hendry, 1923). The United States and Argentina are the world's largest alfalfa-producing countries, but significant land area is devoted to alfalfa in Australia, South and North Africa, Southern Europe, Chile, Mexico, Canada, China, and the Middle East.

Alfalfa is a perennial, autotetraploid, partially self-sterile leguminous forage (Rumbaugh *et al.*, 1988). Alfalfa nearly completely lacks antiherbivory compounds that are common in other plants (a factor that makes it a very desirable forage) but accomplishes defoliation survival through the ability to quickly regenerate shoots. The plant has a 'crown' – a toughened top portion of the root that is capable of generating multiple foliar regrowths through new bud formation. This botanical feature enables alfalfa to be harvested multiple times per year for many years. Alfalfa is typically harvested 3–4 times per year but up to 12 times per year in the desert environments of Arizona, Mexico, and California (Putnam *et al.*, 2008a,b).

Alfalfa is best adapted to deep, well-drained, neutral pH soils but can be grown on clay loam soils if subsurface impediments are lacking (Orloff, 2008). Soil pH is a key limiting factor. A soil pH of 6.5–7.5 is considered ideal and lime is required to grow alfalfa on acidic soils. Alfalfa is deep rooted, with roots commonly in the 1.5–3 m range. As a result, alfalfa is not as easily moisture stressed as are more shallow-rooted forages. High-rainfall areas frequently have difficulties growing alfalfa due to saturated soils and low pH as well as root and foliar diseases. Alfalfa often requires irrigation for maximum yield and therefore approximately 35% of US alfalfa is produced under irrigation. Alfalfa requires significant water annually due to its high yield and long growing season, but it is among the most water-use efficient crops grown under irrigation (Putnam, 2012).

Red clover (Trifolium pretense)

'Red Clover' (*Trifolium pretense*) is a forage legume of European origin used for pasture and hay throughout the cool-season forage regions of Europe and North America. It is the most important *Trifolium* species in North America (Taylor, 1985) and is most frequently grown in mixtures with cool-season grasses and other legumes (alfalfa and white clover) for either hay or pasture. It is grown as a winter annual in the south.

Red clover is a short-lived perennial with a prominent short tap root more branched than alfalfa and forms a 'crown' due to contractile growth, similar to alfalfa, except that crowns are not as deep (Smith *et al.*, 1985). It has an upright growth habit. The primary stem does not elongate, but shoots develop from the crown and axillary buds from lower nodes, but stems do not elongate very much until flower formation. Flowers are of rose to magenta color. Leaves are palmately trifoliate, with oblong wedge-shaped leaflets, typically variegated with a white 'watermark.'

There are two types: 'medium' types, which exhibit earlier flowering, and typically multiple harvests, and 'mammoth,' which flowers much later and typically produces one or two harvests. Red clover is adapted to a wide range of soil types, including moderately poorly drained soils, and tolerates low fertility and moderately acid soils but has low drought tolerance. Red clover is susceptible to root and crown diseases in warm regions.

White clover (Trifolium repens)

'White Clover (*Trifolium repens*)' is a perennial legume of Eurasian origin (Evans, 1976). It is widely distributed from the arctic to the tropics but is best adapted to humid temperate climates (Gibson and Cope, 1985). It performs well under irrigation in drier areas of the Western United States as well. Like red clover, it is sometimes grown as a winter annual in the Southern United States and is dominant forage in New Zealand and many parts of Europe. Bloat can be an issue, but it is usually avoided because white clover is most often grown in permanent pastures in combination with cool-season grasses. The forage is most often grazed rather than hayed. White clover is winter hardy and relatively flood tolerant but is susceptible to drought and high temperatures. Its stoloniferous growth habit makes white clover excellent for soil stabilization.

White clover has a prostrate growth habit and is capable of reproducing via 'stolons,' which are underground stems. Like red clover, the leaves are palmately trifoliate with a variegated 'watermark,' which can be white or red. It has a round seed head with typically white flowers that may have a pinkish coloration as well.

White clover is classified as small, intermediate, or large. The wild types of white clover are small – they are lower

yielding, shorter, and have a more prostrate growth habit. Dutch clover, an intermediate type of white clover, is larger than the wild types. Ladino clover is larger still and is more productive but typically less persistent.

Birdsfoot trefoil (Lotus corniculatus)

'Birdsfoot trefoil (*Lotus corniculatus*)' originally comes from the Mediterranean region. It is adapted to humid, temperate regions and is one of the most drought tolerant forage legumes. It is also adapted to a wide range of soil conditions, including acidity and alkalinity, low fertility, and waterlogged conditions. It tolerates poor drainage better than alfalfa because it is not susceptible to Phytophthora (Beuselinck and Grant, 1995). Unlike many other forage legumes, it does not cause bloat. It is grown throughout much of the world, including Europe, the southern part of South America, and in areas of India, Australia, New Zealand, and the United States.

Birdsfoot trefoil can be prostrate or upright depending on the cultivar. Unlike the other forage legumes that are trifoliate, trefoil is pentafoliate with three of the five leaflets attached to the end of the petiole and the other two near the base. Mature plants have several well-branched stems that arise from the crown. The plant has a well-developed branched tap root that is shallower than that of alfalfa. Plants generally survive only for 2–4 years, so plants are often allowed to reseed to regenerate.

Birdsfoot trefoil has gradually replaced some of the red and white clover use because of it wide adaptation, relatively high yield and ability to reseed. It is typically grown as part of a mixture with grasses.

There are a wide range of additional legumes, both annual and perennial types, that are also grown for forage. **Table 3** lists these legumes, their growth habit, and any unique characteristics or uses. These legumes are less commonly grown than the ones mentioned above and some are grown as rotation crops with row crops or as annuals in pastures that are allowed to reseed.

Forage Grasses

> And I will send grass in thy fields for thy cattle that thou mayest eat and be full
>
> –Deuteronomy 11:15

Agricultural grasses are the basis of not only grain-based agriculture (corn, wheat, rice, and barley) but also stable feedstuffs for nearly all ruminant livestock production systems since farming first began some 12 000 years ago (Williams, 1980). There are cool- and warm-season grasses and each type has species with both annual and perennial life cycles.

Cool-season perennial grasses are usually the primary forage used for beef cattle and sheep production in the United States and throughout the world (Moser and Hoveland, 1996). They are sometimes used in dairy rations but to a much lesser degree. Annual cool-season cereals (such as wheat, barley, oats, and triticale) can also be grown for forage and are most often utilized as hay or silage.

Warm-season grasses, although important in tropical regions, are less common in temperate zones. Most warm-season grasses have a C_4 photosynthetic pathway whereby a four-carbon molecule is the first product of carbon fixation compared with a three-carbon molecule for most plants. This is a more efficient form of photosynthesis and warm-season grasses are typically more productive during the warm summer months. However, they are far more frost sensitive and generally have lower forage quality when compared with their cool-season counterparts.

Cool-season grasses

Ryegrass

Ryegrass, both the perennial form (*Lolium perenne* L.) sometimes called English ryegrass and the annual form (*Lolium multiflorum* Lam.) or Italian ryegrass, is one of the most important grass forages worldwide (Jung *et al.*, 1996). It is indigenous to Europe, North Africa, and temperate Asia. It is a vigorously growing productive species in areas where it is well adapted and is the dominant grazing forage for many parts of continental Europe, the United Kingdom, Ireland, and New Zealand. It is typically the highest quality cool-season grass (Jung *et al.*, 1996). However, it is not as winter hardy as some of the other cool-season grasses and does not tolerate low fertility, moisture stress, or heat stress. It is an important forage grass in areas with mild winters and cool summers, but because it cannot withstand harsh winters its area of adaptation in the United States has been confined primarily to coastal areas of the Pacific Northwest and selected areas in the Northeast and mid-South. It is highly palatable and digestible and therefore is often used for dairy pastures, especially in New Zealand, where it is the principal feed source for dairy cows. Perennial ryegrass is commonly grown in mixtures with white clover and may be grazed or fed as silage or hay.

Perennial ryegrass grows most vigorously during the mild temperatures of spring and fall. It is considered a bunch-type grass. Leaves of perennial ryegrass are folded in the bud in contrast to annual ryegrass where the leaves are rolled. Leaf blades are glossy, which often helps to differentiate ryegrass from other cool-season grasses. The inflorescence is a long narrow spike with 5–40 alternate spikelets that are oriented in the same plane as the rachis.

Perennial ryegrass is considered worldwide to be the premier forage grass due to its superior quality compared with other grasses (Balasko *et al.*, 1995). Ryegrass is not as long lived as other perennial grasses and when used in pasture it persists best when rotationally grazed with a rest period of 2–4 weeks.

Tall fescue

Although there are several different species of fescue used as forages, tall fescue (*Festuca arundinacea*) is the most widely used forage type (Sleper and West, 1996). Owing to its wide adaptation and its excellent persistence, it grew from 16 000 ha in 1940 to >12 million ha by 1973 (Buckner *et al.*, 1979). It was introduced from Europe and is well adapted to humid, temperate zones. It is tolerant to a wide range of stresses, including acidic and alkaline soils, poor fertility, drought and flooding, and heat and cold (not well adapted to extremely cold conditions in high-latitude or high-elevation locations). Tall fescue does particularly well with poorly drained, heavy soil types and withstands water logging. Owing to its broad

adaptability, tall fescue is the predominant forage species throughout the humid transition zone in the United States that lies between 32° and 40° north latitude (Moore, 2003).

Tall fescue is considered a tufted bunch grass but does spread via short rhizomes when grazed or mowed frequently (Sleper and West, 1996). The upper surface of the leaf blade is noticeably ribbed and dull in appearance, whereas the underside is somewhat glossy. The inflorescence is a broad to loosely branched panicle.

An endophytic fungus is known to infect the roots of tall fescue. The endophyte is seed transmitted and enables the plant to better tolerate heat and drought stress and improve persistence. However, endophyte-infected tall fescue produces alkaloids that are toxic to livestock and can cause disorders in cattle and is estimated to cost the US livestock industry hundreds of millions in losses annually (Hoveland, 1993). Endophyte-free cultivars have been developed, but they are less productive in areas where the fungus is prevalent. Tall fescue is commonly grown in pasture mixes in combination with legumes, such as white or red clover. Pastures can be hayed or grazed. Tall fescue tolerates continuous grazing better than most other cool-season grasses and it is the most commonly used forage grass for many beef cattle operations.

Orchardgrass (Dactylis glomerata)

Orchardgrass (*Dactylis glomerata*), native to Europe, North Africa, and parts of Asia, is produced throughout much of the world, including Northwestern Europe, Australia, New Zealand, Japan, and the northeastern portion of United States and the Pacific Northwest. It is widely adapted but best adapted to areas with moderate winters and mild summers and relatively high precipitation or irrigation. It is moderately tolerant to cold, heat, and drought but is more shade tolerant than other forage grasses. In the United States, it was found growing within orchards, giving rise to the name orchardgrass; however, it is also called cocksfoot based on the shape of the panicle (Van Santen and Sleper, 1996).

Orchardgrass is a bunch-type grass, and as the stand ages and thins, pastures can become clumpy. Leaves are folded in the bud and appear flat or V shaped at the base of the leaf sheath, a useful feature for identification. Leaves are light green but often become dark blue green when mature, another distinguishing characteristic of orchardgrass.

Timothy (Pleum pretense *L.*)

Timothy (*Pleum pretense* L.) is often the most sought-after forage for horses and is widely grown throughout northern regions where moisture or irrigation is sufficient. It was reportedly introduced by Timothy Hansen (thus its name) to North America from Northern Europe in c. 1720 and rapidly became the predominant pasture and hay grass for New England and northern states and Canada (Berg *et al.*, 1996). It is well adapted to northern regions with severe winters, due partly to the formation of a haplocorm or a swollen portion at the base of the stem that is used as a storage organ. Timothy is frequently grown in mixtures with legumes (alfalfa and red clover) and is fairly tolerant of flooding and acidic condition and very tolerant of freezing conditions, although not very tolerant of heat and drought (Moore, 2003). On variable soils (with some low-lying areas), mixtures of timothy, alfalfa, and red clover are very effective because the timothy and red clover survive in poorly drained areas, whereas alfalfa often does not. Timothy forms a distinctive, compact seed head and is considered a bunch grass with a fibrous shallow root system but has no rhizomes or other sod-forming structures. Regrowth occurs from haplocorms at the base of the stem. Timothy is an excellent hay crop and highly valued for both cattle and horses; significant quantities of timothy are exported from the Pacific Northwest of United States to Japan and the Far East (Putnam *et al.*, 2013).

Warm-season grasses

There are a range of warm-season grasses that are grown extensively throughout the humid Southern United States below 36° N latitude and in similar warmer regions in the world (Redfearn and Jerry Nelson, 2003). Some are also grown in northern regions, particularly corn silage. A distinguishing characteristic of most of these grasses is a C_4 photosynthetic pathway, which enables rapid growth rates even under hot conditions (MacAdam and Nelson, 2003). Generally, warm-season grasses are very productive under warmer and hot conditions but dormant or nonproductive under cool or winter conditions. In southern cropping systems, warm-season grasses are used primarily for grazing beef and cow-calf production (Pitman, 2007). They are frequently overseeded with annual cool-season grasses to improve winter production.

Although a wide range of warm-season grasses are grown as forages (**Table 3**), the principal and most widely grown warm-season perennials are bermudagrass, bahiagrass, and dallisgrass; and the key annual warm-season grasses are corn and sorghum, although others, such as millets, can also be grown as forages. Most are introduced species to North America, with the exception of native Bluestems, Indian grass, and switchgrass.

Bermudagrass (Cynodon dactylon *L.*)

Bermudagrass (*Cynodon dactylon* L.) is well adapted throughout the southernmost portions of the United States and in similar climates worldwide. It appears in early Graeco-Forman pharmacopeias and was (and is) a sacred grass to the Hindu cultures due to its support of cattle (Harlan, 1976). Bermudagrass lacks significant winter hardiness and is sensitive to freezing temperatures, which limits its growth in far northern regions but grows well in some continental climates, such as the mid-South, Texas, Oklahoma, which have cold winters. Typical of warm-season grasses, growth of bermudagrass begins only in the late spring and is maximized under the hot conditions of summer. It is a sod-forming perennial that spreads by multiple stolons and rhizomes and can be closely grazed. It can be established using seed or stolon cuttings. Bermudagrass tolerates continuous grazing and is often oversown with cool-season annual grasses (e.g., ryegrass) to improve pasture production in the fall and winter and early spring periods (Pitman, 2007). Once established, orchardgrass can tolerate salinity and is adapted to a wide range of soil types (Kaffka *et al.*, 2004). Tifton 85 and other improved cultivars have demonstrated higher quality and yields as well as animal

performance compared with traditional coastal Bermuda types (Hill *et al.*, 1993). Although most common in the southern coastal plains and throughout southern US states, it is grown in the Imperial Valley of California for horse hay, export hay, and seed production.

Bhiagrass (Paspalum notatum *Flugge'*)

Bhiagrass (*Paspalum notatum* 'Flugge') is grown on limited acreage in the southeastern United States. It is a perennial warm-season grass well adapted to the coastal plains of the humid subtropics. It is not as productive as bermudagrass on good soils but is very well adapted to sandy soil types due to its tolerance of drought and low fertility. It is extremely competitive when grown in mixtures, thus difficult to grow with legumes. It forms a dense sod from short, thick rhizomes and tolerates close grazing and continuous stocking. Leaf blades are short and flat or folded with hairy margins, and it has a deep and extensive root system. It is not appropriate for hay making due to the short stature and is often used as a turfgrass (Burson and Watson, 1995).

Dallisgrass (Paspalum dilatatum *Poir.*)

Dallisgrass (*Paspalum dilatatum* Poir.) is grown as perennial warm-season pasture forage in southern regions from Texas to North Carolina and mainly used as permanent pasture. It is best adapted to heavier, moist soils in regions with at least 900 mm of annual rainfall and invades streams and riparian areas in regions with low rainfall. It has a clump-type growth habit and grows well in association with other grasses and legumes and persists under heavy grazing (Burson and Watson, 1995). Dallisgrass is often more difficult to establish than other forage grasses due to slow germination and poor seed quality. Ergot (*Claviceps paspali* Stevens & Hall) can affect the flowers and seed of dallisgrass, and this can produce an alkaloid toxic to livestock.

Corn (Zea mays *L.*)

Corn (*Zea mays* L.), or maize, is not only the most widely grown grain crop in North America but also the most important silage crop for dairies and many beef operations. Corn was domesticated by early Native American farmers in what is currently Mexico, possibly as early as 5000 BCE (Goodman, 1976). It is grown in almost every state of the United States and is very important in China, Africa, South America, and Europe. However, its status as a forage crop, especially as a silage crop, has increased in recent years, due primarily to its high productivity and high energy content of the feed. As a very high yielding C4 grass, corn has few rivals with regard to the combination of high biomass yield and forage quality, particularly due to the high grain component. There has been significant investment from the private sector in genetic improvement for grain (less so for silage), and corn grain yields have famously quadrupled since the 1940s (Nielsen, 2012) – silage crops have been the beneficiary of this improvement. Corn is generally the preferred summer annual forage crop for farms with good soils with neutral pH and sufficient heat units in the warm periods of the summer. Corn is particularly important for dairy farms that have a requirement to recycle manures due to its high nitrogen fertilizer requirement. Silage production has become the mainstay of dairy operations nationally, and acreage has been 6–7 million acres (2–3 million ha) nationally, with production in the important dairy states, such as Wisconsin, California, Idaho, New York, and Pennsylvania, leading US production. As a silage forage, corn is particularly high in energy due to the high grain content of the dry matter (typically 45–55%), and thus satisfies a large portion of the energy needs of lactating ruminants. Corn requires high moisture and fertility, especially N fertilizers. Corn residues (stover) are frequently used for grazing or for baling and storage, especially during drought periods. Optimum forage yields and quality of corn harvested for silage are typically harvested when the seed is between 80% milk line and 7–10 days after black layer formation in the maturing seed (Moore, 2003).

Sorghum (Sorghum bicolor *L.*) and *Sudangrass* (Sorghum × drummondii')

Similar to corn, sorghum is grown predominately as a cereal grain crop, primarily in regions where moisture is limiting – the semiarid regions of the world. However, sorghum is also a significant forage option as a summer annual grazing, silage, and hay crop. Sorghum and various hybrids are one of the most important summer annual warm-season grass options appropriate for forage production in water-limiting regions, especially where corn cannot be grown. Sorghum originated in Africa and was fully domesticated by African farmers, possibly as early as 4000 BC (Doggett, 1976). The sorghum group represents a wide genetic resource, ranging from dwarf high seed-producing milo types to medium-height grain types to nongrain-producing forage-type sorghum to tall tropical types and sorghum–sudan hybrids as well as true sudangrass hay-type varieties. Most sorghum races can be crossed successfully, making hybrids possible. The major groups grown for forage are sorghum, sorghum–sudan hybrids (grown for silage and grazing and greenchop), and sudangrass (grown primarily for hay). The sorghum group is very widely adapted, but its production is limited in colder short-seasoned environments (Moore, 2003). The sorghum group has low tolerance to flooding but is adapted to a wide range of soil types and responds well to fertilizers and irrigation. It is sensitive to cold soils, should be planted when soil temperatures exceed 60° F, and thrives in hot environments when moisture is sufficient. Drought tolerance is accomplished by semidormancy, and the sorghum group is considered to have a lower nitrogen and water requirement than corn. Prussic acid, which can cause cyanide poisoning in livestock, is mostly present in young actively growing tissue. Nitrate accumulation, which can poison livestock, is a risk of sorghum and sudangrass forages, particularly under drought stress, freezing, and high nitrogen fertilizer applications. Sudangrass hay can be harvested four times under irrigation in California and Arizona and has recently entered international commerce by being exported to Japan.

Growth Patterns of Forage Crops

Although there are major differences between species, all forage crops share characteristics of growth and development and yield potential that differ significantly from harvested seed-producing and fruiting crops. The primary difference is the

emphasis on vegetative growth, leafy plant parts, and the harvested component, which in most forage plants is equal to nearly the entire above-ground biomass.

Thus, Harvest Index (HI, or ratio of economic yield to above-ground phytomass yield) of forages is nearly 100%, whereas for most orchard, fruiting, and grain-producing plants, harvest indices ranging from 10% to 55% of above-ground dry matter are observed. This is a major efficiency advantage of forage crops in terms of economic solar capture by crop plants, but, of course, conversion of forage crops requires the additional steps of animal conversion into producing utilizable food products.

Annual forage crops differ significantly from perennials in growth and development, and legumes differ significantly from grasses in both biology and management. Additional differences between species are significant – some are warm-season, whereas others are cool-season crops, some are tolerant of flooding or poor soil conditions, others are not. Thus, farmers frequently must consider a range of forage species to maximize production, given their limitations. Annual forage crop production more closely resembles grain crop production, for example, corn, sorghum, oats, barley, vetches, cowpea, soybean, and other annuals that can be used both as forage and grain-producing crops. However, perennials require unique crop production methods.

Stand Establishment and Early Growth

Nearly all perennial forage crops are small-seeded crops that require considerable attention during establishment (Figures 6 and 7). Many grassy pastures and hay fields are seeded only once in a decade or more, whereas alfalfa and perennially legumes, such as red clover, generally have a shorter stand life of 4–7 years.

After stand establishment, forage plants must grow to full canopy before harvesting begins. For perennials, this generally takes a few months or even a half year before full establishment occurs sufficiently to allow harvesting. Well-developed root systems are important to allow plants to be defoliated and regrow successfully.

Growth Patterns of Forage Crops

Forage species differ significantly in dry matter accumulation over the year. Cool-season grasses produce large biomass during spring (Figure 8) but undergo what is known as a 'summer slump' or reduction in yield during the hot summer months. Thereafter, production often increases again in the cool fall period.

This is in contrast to alfalfa or other legumes. These crops also exhibit higher early season yield and some decrease during warm months, but exhibit a more uniform yield pattern across the year (Figure 8), and most species do not exhibit a significant summer slump. Warm-season forages, however, maximize forage production during the hot summer periods and initiate growth later in the spring. Perennial warm-season grasses begin growth earlier than annuals, but often summer growth rates of productive C_4 annual grasses, such as corn or sorghum, exceed that of perennial warm-season grasses.

Forage Quality

Although yield is the primary consideration for forage production, the quality of the forage is a close second. Forage

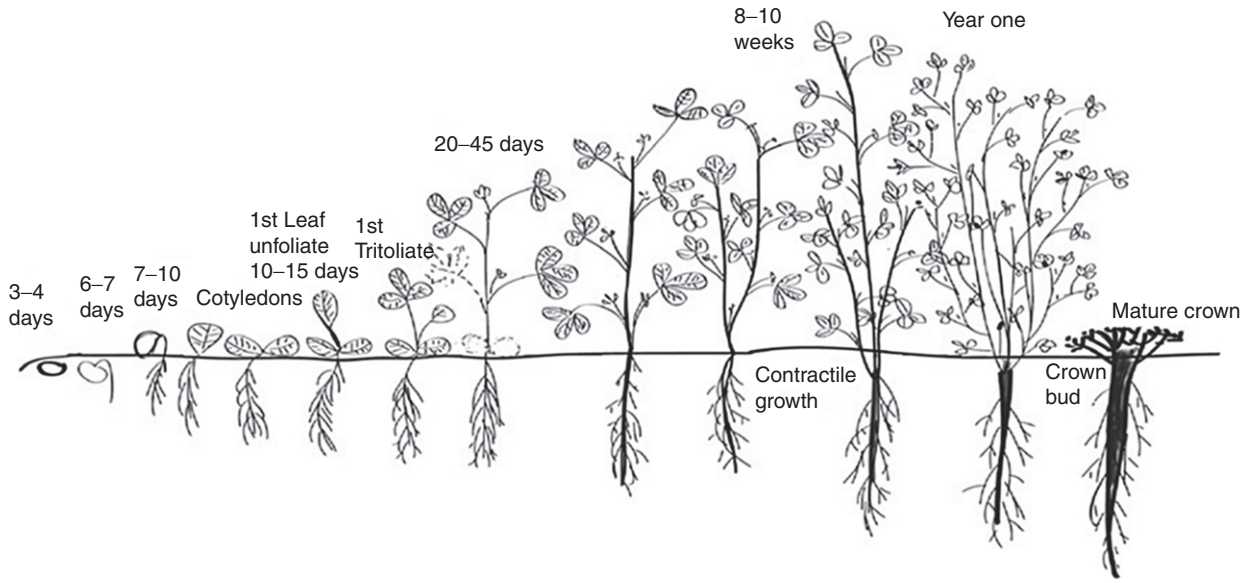

Figure 6 Establishment of an alfalfa plant. Alfalfa develops slowly from a weak annual to a strong perennial over a few months. After seed imbibition (3–4 days) the radicle emerges, pushing downward, after which the first cotyledonary leaves emerge (7–10 days). A single leaf emerges, followed by the emergence of the first true trifoliolate leaves (several weeks). Multiple trifoliolate leaves then emerge, followed by multiple stems from the basal nodes. During contractile growth, the cotyledonary node (2-leaf node) is pulled down into the soil to create the crown, a thickened bud-rich swelling of the root, capable of generating new shoots. The roots must be sufficiently large and deep to store nutrients to sustain frequent harvests (Mohammad Akmal, illustration).

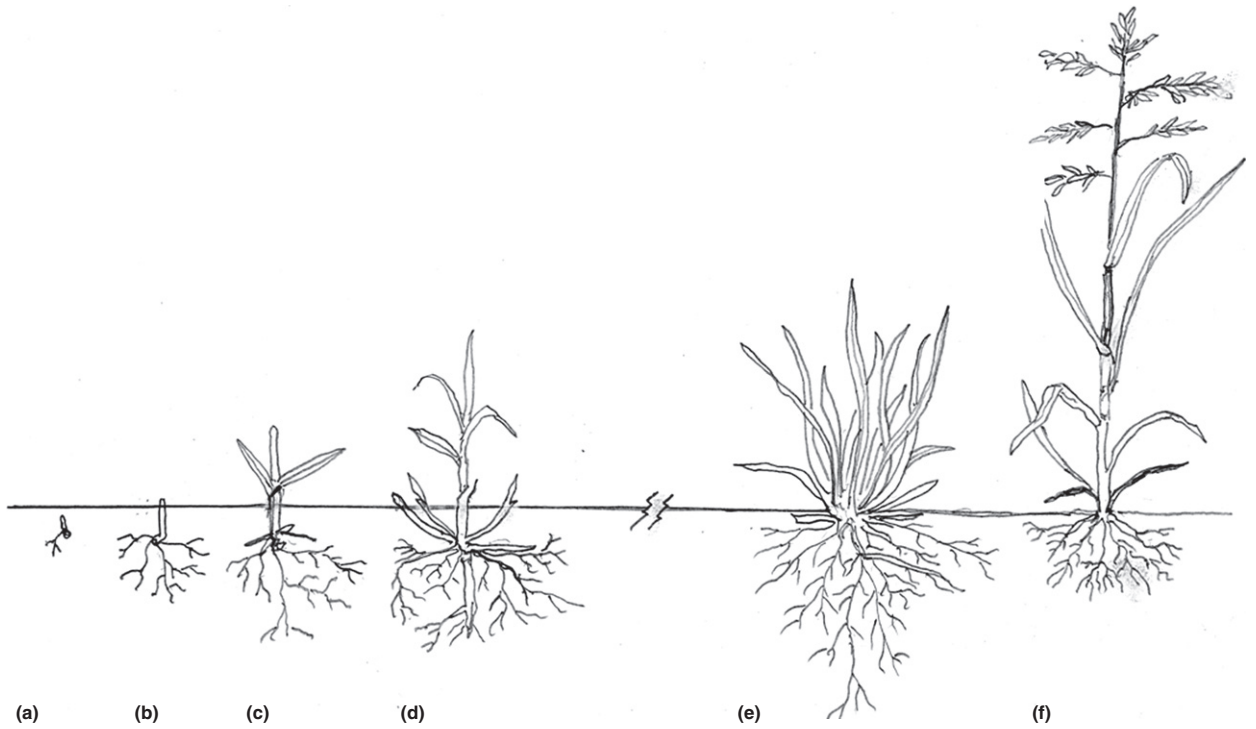

Figure 7 Development of a fescue-type grass. Imbibition of the seed is followed by radicle (root) development (a) and then epicotyl (shoot) emergence. Coleoptile (sheath containing the young shoot) elongation allows emergence from the soil (b), after which the leaf blade extends and the seminal root continues to expand (c). Adventitious roots develop at the coleoptile node (c), followed by the emergence of new tillers developing from basal nodes (d). Adventitious roots develop further, as the seminal root deteriorates. A fully established plant contains numerous tillers, a vigorous adventitious root system, and may produce rhizomes or stolons. During flowering, reproductive tiller growth dominates vegetative growth (f), with new vegetative tillers evident. Adapted from Moser, L.E., Nelson, C.J., 2003.

quality has a large effect on the productivity of forage crops and therefore profitability and economic efficiency of animal production systems. Forage quality impacts animal growth and development and has particular impacts on milk production.

Forage quality has taken on increased importance over the years, particularly for dairy production systems. Average milk production per cow in the United States has improved more than fourfold since the 1920s (**Figure 9**). This is a phenomenal rate of increase in productivity, unmatched by any crop species (with the exception of corn). Although there are many causes for this improvement (animal genetics, veterinary care, cow comfort, management, increased feeding of grains, and concentrated feeds), improvement in forage quality has been a significant factor, accompanied by scientific ration balancing. The process of improvement in animal productivity continues today in the United States (at more than 2% $year^{-1}$ according to USDA-NASS) but is especially apparent in rapidly developing dairy regions of the world that have historically low milk production.

What is Forage Quality?

Although the language of quality is broad, forage quality can be generally defined as the potential to produce a desired animal response from a given intake of forage (Reid, 1994; Ball *et al.*, 2001). As forages are not completely digested by ruminants, the primary considerations are both forage intake (amount consumed per unit time) and digestibility (percent digested – Paterson *et al.*, 1994). Animal response can be measured in the form of milk production, animal growth, meat or wool production, or general health.

Key Attributes of Quality in Forage Crops, listed in approximate order of importance to nutritionists:

- Digestible energy
- Intake potential
- Protein
- Rumen effective fiber
- Minerals
- Lack of antinutritional factors such as noxious weeds and molds

However, forage quality is not an intrinsic characteristic of a plant. The definition and optimization of forage quality depends on both species and class of animal, stage of life, and the mix of feeds in the ration as well as the species and stage of development of the forage plants considered. The best forage for a high-producing lactating dairy cow may not be the best (or most cost effective) forage for a grazing goat, horse, or beef animal. Optimization of quality of oat hay is likely to be different than optimization of quality in red clover. Thus, optimal forage quality is a function of both animal and plant factors.

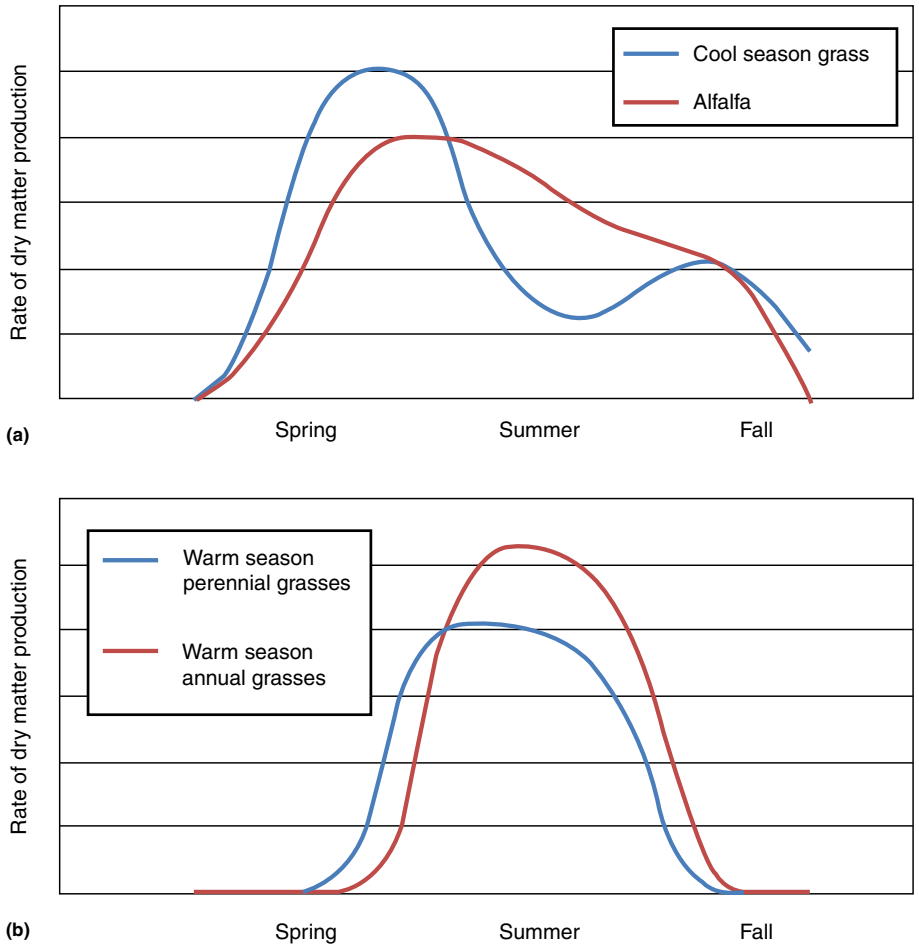

Figure 8 Generalized growth pattern comparison of cool-season forages and alfalfa (a) and warm-season perennial and annual grasses (b). Cool-season grasses typically exhibit very high growth rates, followed by a 'summer slump' and recovery in the fall. Alfalfa yields are highest early but are more even over the season. Warm-season grasses start later, with the highest summer growth rates in the annual C_4 warm-season grasses (e.g., sudangrass, sorghum, and corn).

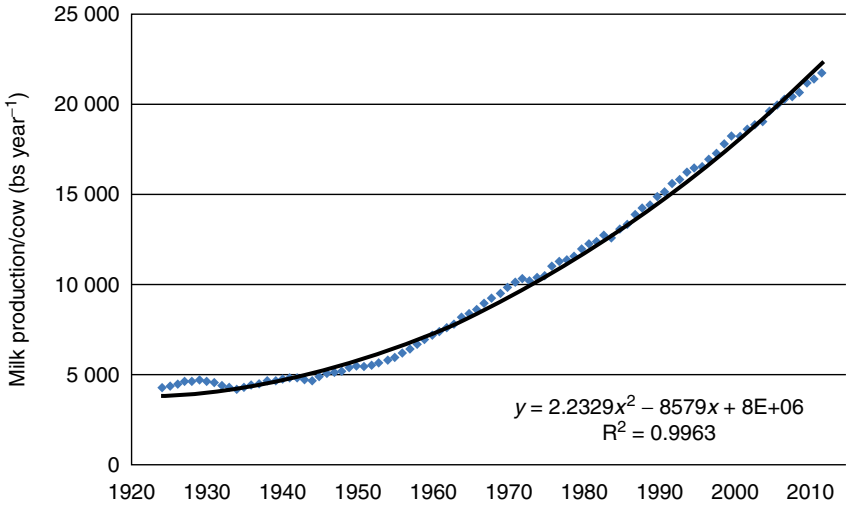

Figure 9 Average productivity of US dairy cows, 1924–2012. The quadrupling of productivity of US dairy cows has necessitated improvement in the quality of forage crops. Reproduced from USDA-NASS. Available at: http://www.nass.usda.gov/ (accessed 09.01.14).

Although it is often tempting to reduce the quantification of forage quality to one or two measurements (e.g., Crude Protein (CP), Metabolizable Energy (ME), Total Digestible Nutrients (TDN) or Relative Feed Value (RFV), see text box for abbreviations), this usually belies a more complicated story. Forage quality is always a complex mix of nutritional traits, including olfactory, chemical, functional, and physical factors. For example, CP concentration is important, but many nutritionists are also interested in the availability (extent and rate of digestion) of the protein. Forages high in digestible soluble carbohydrates and low in fiber (Neutral Detergent Fiber or NDF) are typically desired in forage crops, but NDF itself has important functions in animal nutrition and should not necessarily be minimized, depending on the class of animal and the ration. Furthermore, forages with high-quality analyses may contain toxic weeds or molds with toxins that degrade quality or physical attributes that lower palatability.

Forage quality terminology

Acid detergent insoluble nitrogen (ADIN) The nitrogen fraction in the ADF residue, generally unavailable for digestion by livestock, often due to heat damage.

Acid detergent insoluble crude protein (ADICP) It is calculated from ADIN (ADIN × 6.25).

Acid detergent fiber (ADF) The most difficultly digested fibrous portion of the plant that includes lignin and cellulose and silica, but not hemicellulose. ADF is a subset of NDF.

Ash A measure of the total mineral content of a sample, the residue remaining after burning a sample.

Cellulose A structural carbohydrate, long-chained polymer of glucose with 6 carbons, a major constituent of cell walls.

Crude protein (CP) An estimate of nutritionally important protein calculated from % nitrogen in crop (6.25 × %N).

Dietary cation–anion difference (DCAD) Calculated as a ratio of positively charges and negatively charged, divalent and monovalent mineral ions in a feed.

Digestible energy (DE) The energy in a forage that is not excreted in feces.

Dry matter (DM) The percentage of the crop that is not water. All rations and forage quality are considered on a 100% DM basis.

Ether extract (EE) A laboratory measurement of crude fat (lipid) content of plant material.

Hemicellulose Long chains of 5-carbon sugar compounds, an important component of plant cell walls.

***In vitro* digestible dry matter digestibility (IVDMD)** An *in vitro* bioassay utilizing rumen fluid estimating the amount of forage dry matter which is digestible in a length of time (e.g., 24 or 48 hours).

***In situ* digestibility** Digestibility of a feed determined *in situ* by incubation in a nylon bag within the rumen of an animal for a fixed time period.

Lignin The largely indigestible plant cell wall component, giving the plant stem its strength, reduces digestibility in forages.

Metabolizable energy (ME) The energy in a forage not lost in feces, urine, or rumen gases.

Net energy of lactation (NE_l) An estimate of the energy value of a feed used for maintenance plus milk production.

Net energy for maintenance (NE_m) An estimate of the energy value of a feed to maintain an animal at a stable weight.

Net energy of gain (NE_g) An estimate of the energy value of a feed that may be uses for weight gain above maintenance.

Neutral detergent fiber (aNDF) A fiber measurement which generally includes most of the cell wall material, cellulose, hemicellulose, and lignin (but not pectin); ADF is a sub-set of NDF. aNDF indicates amylose-included NDF procedure.

NDF digestibility (NDFd) An *in vitro* bioassay utilizing rumen fluid estimating the digestibility of the NDF fraction in a given length of time (e.g., 24 or 48 h).

Nonfiber carbohydrate (NFC) An estimate of the rapidly available carbohydrates in a forage (sugars, starches), calculated as a difference (100- ash%, NDF%, CP%, EE%).

Nonstructural carbohydrates (NSC) A measurement of the easily digested starch and sugar components of forages.

Relative feed value (RFV) An index for ranking cool-season grass and legume forages, calculated from ADF and NDF.

Relative feed quality (RFQ) An index for ranking cool season grass and legume forages, based primarily upon NDF, NDFD, ash, CP.

Rumen undegraded protein (RUP) The portion of CP not degraded in the rumen, sometimes called 'bypass protein.'

Total digestible nutrients (TDN) The sum of CP, EE (multiplied by 2.2), nonstructural carbohydrates, and digestible NDF. TDN is often calculated as a linear function of ADF.

Undegraded intake protein (UIP) The amount of forage protein that passes undegraded from the rumen.

There are, however, some major nutritional requirements for animals that are expected from forages that are important for nearly all class of animals. These are listed in approximate rank, but the relative importance will likely change with animal type, stage of life, and feed ration formulation. Forage quality is most often defined in terms of milk production of high-producing dairy cows. However, these factors are relevant to varying degrees to all classes of animals.

Digestible energy

In most cases, the primary consideration for forage quality is the potential DE per unit of forage dry matter. The supply of energy in feeds is a function of digestion and absorption of energy-containing compounds in the plant. This is usually considered very important as biological energy drives all animal functions of maintenance, growth, and milk production.

In forage plants, digestible energy comes from both rapidly and slowly available sources. The rapidly available forms include sugars, starches, and pectins, which are released quickly in the rumen and contribute energy to the animal. However, considerable energy in forages is contained in the cell wall (cellulose and hemicellulose), which is made available only through enzymatic breakdown by rumen microorganisms. These are also subsequently converted into volatile fatty acids and absorbed by the animal. Although starches, sugars, and pectins are essentially 100% digestible, the fibrous energy component in the alfalfa cell wall is typically only 30–70% digestible.

Unfortunately, the total potential biological energy in feeds cannot be easily measured directly with routine analyses, because it is a function of both the forage and the animal but is predicted with equations derived from several laboratory analyses. Energy (TDN), net energy (NE), net energy of lactation (NE_l), or Metabolizable Energy (ME) can be predicted from a linear relationship to a fiber measurement (ADF or

NDF, forage specific) or by summative equations involving a number of measurements. Energy is more accurately calculated from summative equations that use amylose-included NDF (aNDF), neutral detergent fiber digestibility (NDFd), ash, ether extract (EE), CP, and other factors to predict energy. This includes an *in vitro* analysis utilizing a rumen fluid bioassay (NDFd or *in vitro* digestible dry matter (IVDDM)).

Intake potential

Forage intake is one of the most critical quality components of forages and differs significantly between species and within species due to maturity and other factors (Mertens, 1994; Paterson *et al.*, 1994). Of the differences in digestible dry matter among animals and feeds, 60–90% are related to differences in intake (Reid, 1961). Some forages are digested very rapidly in the rumen, whereas other feeds require extended periods for complete digestion. At the extremes, straws have very low rates (as well as extent) of digestion compared with leafy leguminous forages, such as immature alfalfa. These differ greatly in their NDF content and NDF digestibility as well as rate of passage. High-fiber forages may also have slow fiber digestibility – therefore, animals can become 'full' and stop eating. However, NDF content is not highly correlated with NDF digestibility (Putnam and Undersander, 2006). Rumen fill limits intake, which ultimately reduces energy intake (per unit time) and animal performance. However, too low fiber (or NDF) content also creates acidosis and other medical problems in livestock (Mertens, 2010).

There are other factors as well that influence animals' intake of a forage, often termed 'palatability,' which are affected by species, taste, physical condition of the hay, odor, weed content, stem quality, and plant maturity.

There are several approaches to measuring, or predicting, rumen digestibility, including IVDDM, *in vitro* gas production estimates, *in vitro* NDFd, and *in vivo* (in the rumen) fiber disappearance, all of which are bioassays involving digestion of a sample in rumen fluid. Intake potential is one of the most important quality factors for lactating dairy cows (Paterson, *et al.*, 1994).

Protein

As amino acids from proteins are building blocks for muscle, milk, and animal enzymes, they are important nutritional attributes of forages. Sources of protein absorbed from forages are from two major sources: protein synthesized by rumen microorganisms and protein that escapes rumen degradation (Broderick, 1994). Although the concentration of protein (estimated by CP) is important, many nutritionists may also be interested in the amount of forage protein that passes undegraded from the rumen (undegraded intake protein, UIP) and is digested in the small intestine. Additionally, protein can be too closely associated with cell wall fibers and rendered nondigestible. Acid detergent insoluble CP (ADICP) estimates the undigestible (typically lignified and heat damaged) CP. In addition to heat damaged and undegraded protein being a negative factor, excessive degradation of CP in the rumen is also a negative quality factor if the rumen microbes do not fully utilize the ammonia nitrogen (N) for microbial protein. This excess ammonia N is absorbed through the rumen wall, and much of the ammonia is converted into urea via an energy-dependent process, which is then excreted in the urine. High rumen degradable protein can be a problem with very leafy immature forages, and these highly digestible proteins can lead to bloat in ruminants.

Ruminally effective fiber

The provision of ruminally effective fiber with a high level of digestibility is a major attribute provided by forage crops in ruminant rations, especially those with high grain additions. In addition to high fiber (NDF) being a problem for forages, as it limits energy and intake, low fiber is also a problem, as effective NDF is a valuable component of forage crops (Mertens, 1994; Mertens, 2010).

Energy and intake are generally inversely related to fiber concentration (ADF and NDF) in the hay, particularly energy available per unit time in the rumen. Thus, as the percentage of ADF or NDF goes up, digestible energy and intake go down. As a result, dairy managers frequently demand low-NDF or low-ADF hays. However, reduction of fiber to very low levels can create problems in rumen function because dietary fiber stimulates rumination, chewing, and saliva production; the latter helps to stabilize rumen pH. High-producing ruminants can suffer physical problems with rumen health when 'effective fiber' is too low in their diet. Thus, the fiber in forage crops provides positive physical and chemical attributes to ruminant rations. It is clear that both the concentration of the NDF and the rates of digestion of the fiber fraction (estimated by NDFd) are important attributes of forage quality.

Ash and minerals

Ash is an estimate of total mineral content in a forage, which could originate from normal mineral uptake by the plant, for example, phosphorus (P), potassium (K), sulfur (S), calcium (Ca), magnesium (Mg). Ash can also result from excessive salt accumulation or contamination with soil. In general, as ash increases, the level of digestible energy declines, because minerals do not contain energy. Thus, ash is considered to be a negative factor in predictions of energy for ruminants, and lower ash forages should generally contain higher energy.

However, forages provide several essential minerals contained in the ash fraction. Mineral ions such as Ca, P, and K in forage may be important nutritionally, but it is also clear that may be easily supplied as a supplement to most livestock if deficient.

Some minerals may be negatives for animal nutrition. High K concentration is a negative attribute for dairy animals just before and after calving (often termed the 'close-up' or 'transition' period), as excessive K contributes to an increased incidence of milk fever (postparturient hypocalcemia). Additionally, excessive concentrations of micronutrients (such as selenium [Se] or molybdenum [Mo]) can be toxic when present in high amounts in the diet. Conversely, forages can provide necessary micronutrients that otherwise might be limiting in diets. Nutritionists are often interested in the balance of mineral nutrients in forages (DCAD, see text box).

Other quality factors

There are visual, textural, and olfactory attributes of forage quality that are not easily analyzed in laboratories. The presence of noxious weeds, foreign objects in hay or silage, dirt, secondary plant compounds, aromas or odor, dust, and molds, all may affect animals' performance. Insects (e.g., blister beetle) can be important antinutritional or toxic factors in hay. Each year, many animals are sickened or die from poisonous weeds, excess nitrate (from weeds), botulism (from dead animals), or excess micronutrient concentrations in hay (Puschner *et al.*, 2006). These are all attributes under the umbrella of 'forage quality.'

There are also physical aspects that affect quality (e.g., grind, fiber length, and moisture). Particle size affects the ability of rumen microbes to break down cellulose and hemicellulose in the rumen (Mertens, 2010). Olfactory factors (e.g., odor, dustiness, and chemical attractants that encourage uptake) can influence intake. Contaminants (e.g., toxic weeds, dirt, molds, and toxic insects) can affect palatability, intake, and thus overall quality. Several subjective factors (e.g., visual inspection, touch, and smell) may assist in predicting animal acceptance, but palatability may be less important in total mixed rations (TMRs), because other feeds and additives impact voluntary intake by ruminants.

It should be clear from the above discussions that forage quality is a complex trait that includes a range of factors. These factors are, in turn, influenced by agronomic and environmental factors.

What Influences Forage Quality in Crop Plants?

Forage quality is a function of both species (grass, legume, etc.) and variety within species as well as various management practices (Rotz and Muck, 1994; Ball *et al.*, 2001). The major agronomic factors that affect quality are species (e.g., legumes vs. grasses, warm season vs. cool-season crops), cutting frequency (plant maturity at harvest or grazing), weed and pest management, baling and conditioning effects, and seasonal or weather patterns (Buxton and Fales, 1994; Ball *et al.*, 2001; Putnam *et al.*, 2008a,b). Less significant but still important are the effects of variety, time of day of harvest, soil type, fertility, and irrigation. These factors typically affect quality via two fundamental mechanisms: the leaf:stem ratio and effects on cell structure. Agronomic and environmental factors have a strong influence on total yield and there is normally an inverse relationship between yield and forage quality.

Plant Maturity at Harvest

It is a nearly universal axiom of forage production that as a plant grows and develops, forage quality declines. Immature herbage growth is nearly always higher in quality than more mature forages (Marble, 1974). Therefore, the stage at which the plant is harvested is usually the most critical factor determining forage quality in nearly all forage crops. The exceptions to this rule are seed-producing forage crops, such as corn or sorghum, grain legumes, and small grains that translocate nutrients (protein, starch, and oils) to seeds, but even in those plants, immature vegetative growth is higher in quality than late vegetative growth.

Plant morphology

The change in forage quality due to plant maturity is the result of several powerful mechanisms. First, immature plants tend to be much higher in leaf percentage (**Figures 10** and **11**). Leaf percentage declines as the plant grows, as a percentage of the total plant biomass. In alfalfa, this is primarily due to the increase in stem weight that occurs during growth. In most grasses, tillering and reproductive stages also produce multiple flowering culms that are lower in quality than the leafy immature crop.

The decline in forage quality in alfalfa and many grasses is also due to a reduction in the quality of the stems with advancing maturity. In alfalfa, this is approximately a 0.5 percentage point decline in digestibility (IVDDM) per day, which increases dramatically in NDF and ADF, whereas the quality of leaves declines only very slightly over time, especially in legumes (**Figure 10**).

Additionally, there are changes that take place on the cellular basis. Cell solubles are reduced with plant maturity. These are sugars and soluble proteins that are essentially 100% digestible and decline with maturity. Secondly, the stem fraction develops much more secondary wall (increased lignification and lignin–cellulose complexes), reducing the digestibility of the cell wall fraction as the plant matures.

The NDF fraction reflects cellulose, hemicellulose, and lignin, whereas the ADF fraction largely measures cellulose and lignin (**Figure 11**). As a plant matures, secondary cell wall development leads not only to a higher concentration of NDF but also to fiber that typically becomes more poorly digested in ruminants.

Factors and principles that influence alfalfa quality:

Primary mechanisms
- Plant maturity at harvest
- Leaf percentage
- Mixture with weeds
- Environmental effects

Agronomic factors
- Cutting schedules
- Harvest management
- Rain damage
- Time of day for harvest
- Variety
- Irrigation and soil factors
- Pest interactions

For these reasons, cutting schedule is, overwhelmingly, the most powerful method under a grower's control to manipulate forage quality for herbaceous forages, as both maturity and leaf percentage and even weed intrusion are impacted. In alfalfa, growers have generally gravitated toward early- to late-bud harvests to attain high forage quality, but at great expense of yield and persistence (**Table 3**).

If yield, stand persistence, and weeds were not important, the earliest cutting dates would typically provide the highest

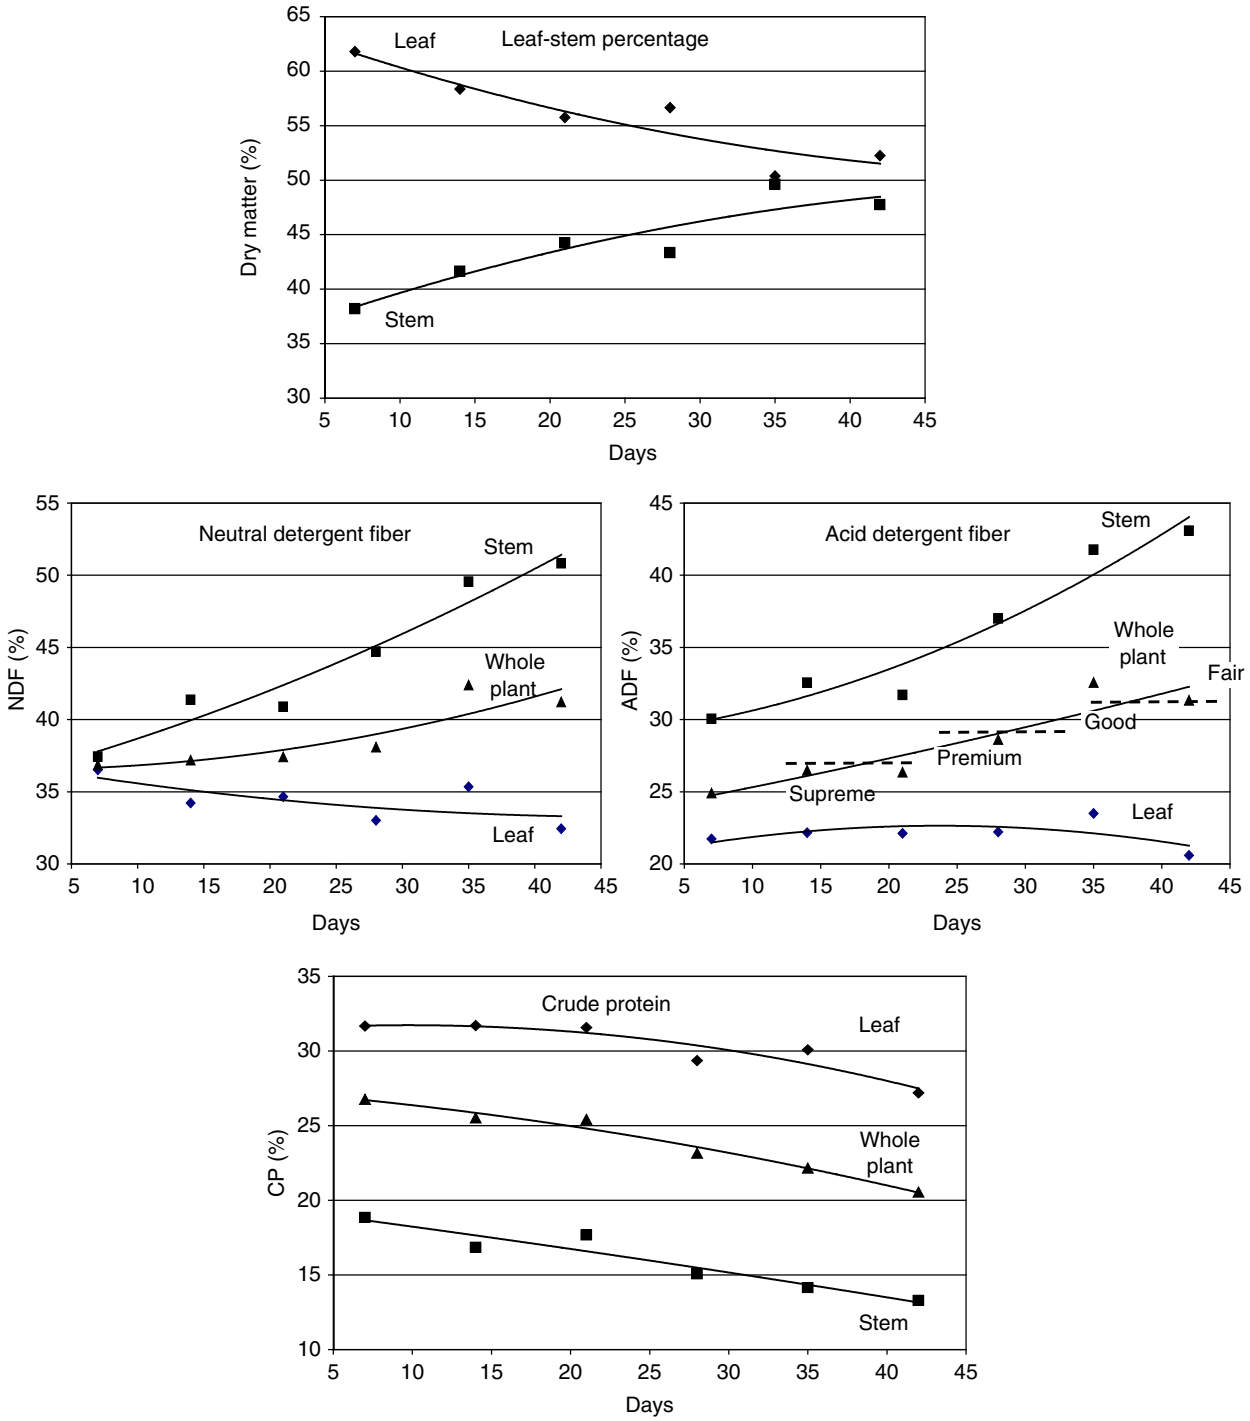

Figure 10 Plant maturity effects on alfalfa dry matter percentage, acid detergent fiber, neutral detergent fiber, and crude protein concentrations of the first growth period, Yolo Co., CA. 'Supreme,' 'Premium,' 'Good,' and 'Fair' are market guidelines as per USDA-Market News. Reproduced from Ackerly, T.L., 2001. Characterizing and predicting the yield/quality tradeoff in alfalfa. MS Thesis. University of California.

quality forage, but this would rarely provide optimum economic returns. The vigorous cutting schedules commonly practiced to attain high quality may ultimately work against high-quality production because stands may thin and weeds may invade (Table 3). Although forage quality is dramatically improved by short cutting schedules (e.g., 21-day intervals), yield is also dramatically reduced, as is stand life, allowing for increases in weed infestation (Table 4). The optimum profitability point as determined by cutting schedule is almost never the point where maximum quality is obtained, nor at the point where maximum yield is obtained (Marble, 1974; Orloff and Putnam, 2010). Clearly, a more integrated

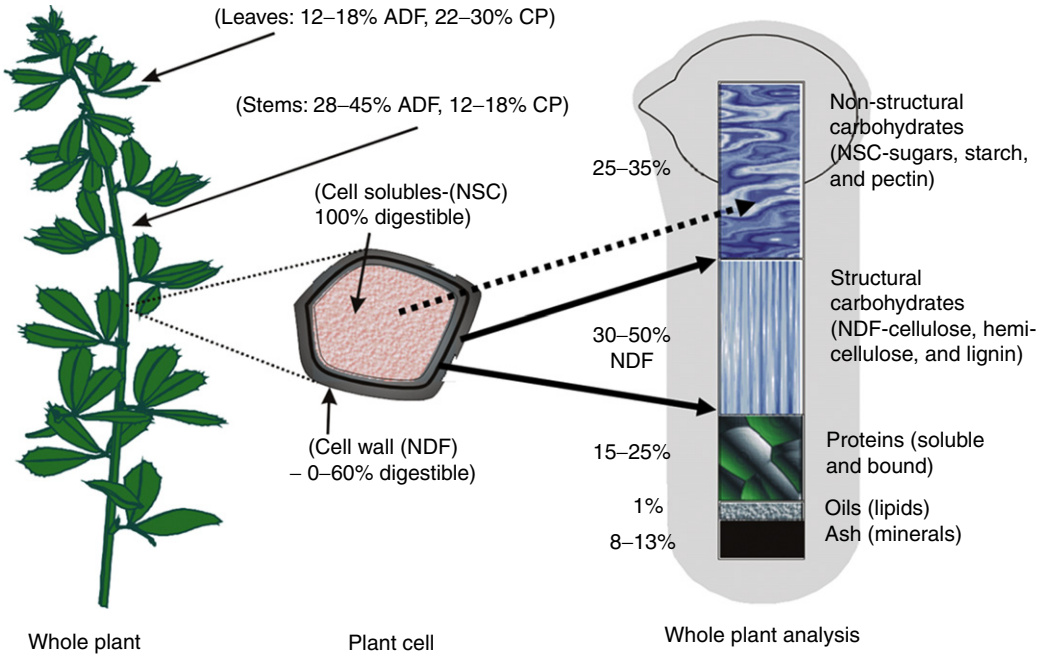

Figure 11 Forage quality (for example in alfalfa) is influenced by both morphological factors (e.g., leaf/stem ratio) and cellular factors (development of the fibrous cell wall and cell-soluble content). Important laboratory measurements for forages include NDF and ADF (structural carbohydrates), crude protein, and ash, as well as *in vitro* NDF digestibility or total DM digestibility. Nonstructural carbohydrates are typically measured indirectly as nonfiber carbohydrates by subtraction from NDF, protein, ash, and lipid. Lipids do not vary much in herbaceous forages and are generally not measured.

Table 4 Effect of maturity at harvest and harvest interval on alfalfa yield, quality, leaf percentage, weeds, and stand life (data from Davis, CA)

Maturity at harvest	*Harvest interval (days)*	*Yield (tons per acre)*	*Acid detergent fiber*	*Crude protein*	*Leaf*	*Weeds*	*Stand percentage*[a]
			%				
Pre-bud	21	7.5	26.3	29.1	58	48	29
Mid-bud	25	8.8	29.5	25.2	56	54	38
10% bloom	29	9.9	32.2	21.3	53	8	45
50% bloom	33	11.4	32.7	18.0	50	0	56
100% bloom	37	11.6	35.5	16.9	47	0	50

[a]Percentage of alfalfa stand after three harvest years.

approach balancing yield, quality, persistence, and economics is required.

The process of drying, raking, handling, baling, and storage of forages has long been known to have large effects on forage quality (Rotz and Muck, 1994). For leguminous forages like alfalfa, the leaves dry much faster than stems, and hay is often baled at a point where leaves are too dry for handling. Leaf shatter during haymaking is a significant hazard during harvest and can reduce forage quality by reducing leaf:stem ratio. Any method, irrespective of whether it is mechanical-intensive conditioning, chemical conditioning, wider swath width, or skillful raking that speeds the drying process of stems, may improve forage quality. Grasses tend to be far less sensitive to leaf loss during haymaking than are legumes.

Environmental Services of Forage Crop Systems

> Our goal is permanency in agriculture – an agriculture that is stable and secure
>
> –GRASS – The Yearbook of Agriculture, 1948, USDA

More than any other crop group, forages provide a range of important environmental services that largely escape notice by the general public. The diversity of legumes, grasses, and forb forages support wildlife habitat, build soil quality, stabilize soils from erosion, purify the air and prevent dust pollution, prevent degradation of water quality, suppress weeds, recycle nutrients, provide crop rotation benefits, and assist in mitigation of environmental problems, such as nitrate pollution and greenhouse gas accumulation (Barnes and

Nelson, 2003; Wedin and Russelle, 2007; Karlen *et al.*, 2007; Keeney and Sanderson, 2007; Franzluebbers, 2013; Putnam *et al.*, 2001). Legumes like alfalfa provide a profound service by producing high nitrogen-containing protein with nearly zero fossil fuel-requiring N fertilizers, unlike corn, rice, wheat, and grain crops that use huge quantities of N fertilizers.

However, there are environmental risks and impacts of forage crops that must be considered. Manures are a risk to grazing lands, pasture, and CAFOs, and nitrate contamination of groundwater and air quality problems have been associated with many animal production areas. Forages themselves may provide risks to the environment through crowding out native species (vigorous pasture grasses), or from pesticide runoff (alfalfa).

However, on balance, there are clearly many more environmental services from forages than negatives (Putnam, 2010). Forages have numerous ecological attributes to support robust and sustainable agroecosystems, irrespective of whether they occur as managed forage systems, naturalized grasslands, or native prairies. Perennial grasses and legumes are particularly important to landscape health and sustainability, in addition to providing significant quantities of human food. These services fall into several categories.

Soil Erosion Control

Soils formed under vast grasslands, such as the Central Great Plains of the United States, are very rich, due primarily to the grass ecosystem that builds organic matter over many millennia (Barnes and Nelson, 2003). But in the short run as well, grasses and legumes help to build soil quality due to the many rhizosphere biological interactions (micro- and macroorganisms) and their ability to firmly hold soil in place. The dense forage canopy and extensive rooting patterns prevent both water and wind erosion, and rooting channels provide habitat for invertebrates and create stable aggregates and biopores, furthering plant growth. This landscape provides protection from sheet and rill erosion in agricultural landscapes (**Figure 12**). The value of forage crops to prevent soil erosion, long promoted by the US Soil Conservation Service (now Natural Resources Conservation Service), is a well-established environmental service of forages. Many environmentalists and agronomists have promoted the incorporation of forage legumes and grasses into row crop rotations for their soil building and conservation properties.

Water-Use Efficiency, Water Quality, and Mitigating Water Pollution

Perennial forage crops are highly beneficial for water quality and are highly water-use efficient. Perennial forages grow rapidly after rainfall or irrigation events and capture utilizable water in the root zone due to extensive and deep rooting patterns. Unlike annual crops, which must utilize water during stand establishment to achieve a full canopy, forages begin growing quickly. Dense plant, surface residue, and rhizosphere create stable surface soil aggregates, assisting water infiltration and percolation (Karlen *et al.*, 2007). The extensive root system, fully canopy, combined with the fact that 100% of the above-ground dry matter is harvested, make forage crops one of the most water-use efficient crop species (Putnam, 2012).

Further, water with suspended solids is purified in grassy or leguminous forage stands, benefitting both surface water and groundwater. 'Grassed waterways' are commonly recommended for erodible areas in row crop production systems, but pastures and hay fields themselves serve as natural filtering buffers to improve water quality (Karlen *et al.*, 2007).

Nitrate pollution of groundwater is a frequent concern of agricultural communities. Forage crops, particularly productive grasses and alfalfa, are excellent at absorbing nitrates from

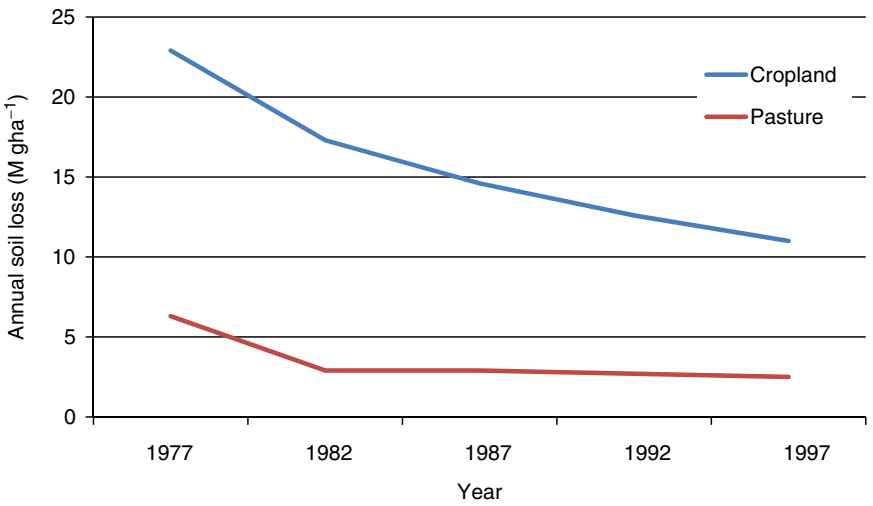

Figure 12 Effects of row crops versus pasture on annual soil erosion losses in Iowa. Although no-till techniques have reduced row crop effects on erosion in recent years, pastureland provides permanent protection for soils. Data from USDA-NRCS, 2007 National Resources Inventory (USDA, 2009).

municipal wastes and from manure sources (Wedin and Russelle, 2007). In the case of alfalfa, N uptake may range from 300 kg ha^{-1} to 900 kg ha^{-1}, depending on yield and protein content of the forage.

Air Quality, Dust Prevention, and Greenhouse Gasses

Productive forage crops generate oxygen and absorb CO_2 from the atmosphere. Additionally, forage canopies protect soils from wind erosion, due to the perennial nature of forages and their vigorous rooting patterns. Protection of erodible soils by forages in windy regions has been widely promoted. Depending on the degree of N fertilizers used, moisture regime, and the animal management system, forage systems can either have positive impacts on greenhouse gas production or have negative impacts (Keeney and Sanderson, 2007). The clearing of grassland sod has been widely recognized as releasing large stores of CO_2 as well as N_2O. Thus, tilled cropping has resulted in carbon losses in plowed prairies, resulting in losses in organic matter concentration of 50–70% (Lal *et al.*, 1998). Whalen *et al.* (2003) found that continuous wheat resulted in 30–39% carbon losses compared with native grassland after just 5 years.

Nutrient Cycling

Deep-rooted forages, such as alfalfa, tend to cycle nutrients from depth, in comparison with row crops (Wedin and Russelle, 2007). Cycling of nutrients under perennial forages are often characterized by a high proportion of nutrients in the organic form compared with annual grain crops. This makes nutrients less susceptible to leaching through the soil (nitrate loss) or dissolved fractions in surface runoff or volatile losses to the atmosphere through denitrification. Soil microbial biomass and N mineralization can be significantly greater under forages than row crops, which improves both nutrient cycling and soil tilth (Arshad *et al.*, 2004).

Wildlife Habitat and Biodiversity

Forage crops are the primary producers at the beginning of a food chain that supports a wide diversity of insects, invertebrates, lizards, mammals, and birds. Alfalfa, which is very high in nutrient value, can support up to 1000 species of insects, most of which do not negatively affect its growth. Grasslands are important providers of wildlife habitat and open spaces worldwide (Franzluebbers, 2013). Migratory waterfowl, raptors, songbirds, and wading birds often prefer forages to even natural landscapes due to the diversity of insects and prey, cover, and stability (Putnam *et al.*, 2001). Endangered or species of concern, such as the Swainson's Hawk, long-billed curlew and, white faced ibis, have been found to prefer alfalfa fields over other landscapes (Hartman and Kyle, 2010). Larger wildlife, such as elk, deer, fox, coyote, snakes, utilize forage fields extensively. Of the >600 species that are listed in the California wildlife database, >28% utilize alfalfa for feeding, cover, or reproduction (Putnam *et al.*, 2001).

The future of forage crops will likely depend both on their important role as a food-producing agroecosystems and the provision of ecosystem services.

From Foraging to Agriculture

L Grivetti, University of California, Davis, CA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Adjustment equilibrium Food supply balance achieved between small bands of hunter-gatherers and food available in a given ecological setting.

Annual round of activities Seasonal migration practices of hunter-gatherer bands as they search for food throughout their territories.

Competitive Foraging Strategies Systematic study and analysis how nonhuman primates and contemporary human hunting-gathering bands search for, identify, and forage for food.

Geophagia The practice of consuming clay as a food.

Incipient planting Condition where wild species are removed from bush lands, and either seeded or transplanted adjacent to human settlements for ready access as food or for other utilitarian purposes.

Toxic analogs Describes the condition where a species is safe to consume in one environmental niche but poisonous in another.

Introduction

In the Beginning

The domestication of plants and development of agriculture are relatively recent activities in the vast time span of hominid and human evolution. Scholars interested in these topics have posed and debated a variety of questions for more than a century: how did earliest hominid groups and subsequent human hunting-gathering bands determine what was safe to eat; procure their food resources; and satisfy their basic physiological/health requirements? In subsequent millennia, what factors facilitated the decision for earliest human settlement, stimulated incipient planting, and the development of agriculture? During the long, evolved passage from hunting-gathering livelihoods to settled agriculture, how and why were certain plants selected and ultimately domesticated?

A basic consideration in understanding agriculture and plant domestication is separating conscious from unconscious decisions: human settlement and the development of agriculture were conscious choices whereas initial plant domestication processes were not. In essence, individuals and early hunter-gatherer bands decided to cultivate; they did not decide to domesticate crops because it was the basic process of selecting and gathering wild plants that initiated the steps toward domestication. Plant eco-niches were modified through time as hominids and early humans foraged and selected their respective food and nonfood items from vast arrays of plant assemblages. Domestication has been a long-standing, continuous, unconscious process that predates human settlement and agriculture, as visualized in the following schematic (Figure 1).

Consensus suggests that human-like hominids developed initially in the warm tropical savannah regions of what is now east Africa perhaps 2.3 million years ago (Clark, 1980; Strait *et al.*, 1997). Much speculation has surrounded the presumed primary food patterns of these early hominids: were they vegetarians, meat-eaters, or omnivores? The answer, however, is seen on inspection of jaw and teeth structures of both ancient hominids and modern human descendants: both groups exhibit characteristic molars for seed grinding and shortened canines, a dental pattern that reflects a mixed diet of both plant and animal foods (Le Gros Clark, 1955; Jolly, 1970; Isaac, 1971; Walker, 1981; Teaford and Ungar, 2000; Rodman, 2002; Ungar and Teaford, 2002; Unger *et al.*, 2006).

Long after the initial stages of plant domestication humans settled and subsequently planted and tended crops. What has been called agricultural revolution occurred at different times globally at widely separated geographical locations. Earliest evidence for settled agriculture stems from East Asia in a geographical zone encompassed today by southwestern China and northwestern Vietnam and Laos during what is called the Hoabinhian Period, dated to c. 15 000 BCE (Gorman, 1969, 1971; Solheim, 1972). Dates for settlement and agriculture in the so-called Fertile Crescent of the Middle East are somewhat later, attributed to c. 11–8000 BCE (Zohary and Hopf, 2000), whereas settlement and plant domestication in different parts of the New World, specifically in Mexico and the highland Andes region, date to 6000 BCE and 4000 BCE, respectively (Bellwood, 2005). Because early human-like hominids

 doi:10.1016/B978-0-444-52512-3.00232-1

evolved more than 2 million years ago, for the vast majority of time they hunted, foraged, and scavenged for food.

Ethnographic studies of modern twentieth and twenty-first centuries hunter-gatherer societies offer complementary insights on the early human quest for food. Such groups throughout antiquity into the twenty-first century are defined uniformly by their lack of agriculture and domesticated plants or animals (save the dog) and by food patterns based solely on plant and animal bush products that are highly diverse and varied (Heinz and Maguire, 1974; Lee, 1979). Such hunting-gathering groups in the twenty-first century exist in narrowly defined regions of Asia, Africa, the Americas, and Oceania where small bands usually numbering less than 40 individuals follow their traditional lifestyles through what is called the annual round of activity, a repetitive migration pattern through different ecological zones where the hunter-gatherer bands follow wild game and gather plant products (Anderson, 2004). Such groups eke their livelihood through a mix of gender-specific activities where adult males primarily hunt, while adult women and girls primarily gather plants and plant products, although exceptions are known where women participate in hunting activities and adult males sometimes participate in gathering plants/plant products. Although these small groups commonly are known as hunter-gatherers, in reality female gathering activities commonly provide the vast bulk of food resources for the band, a behavior that suggests more realistic terms such as collector-predator or gatherer-hunter societies should be applied (Dornstreich, 1973; Hiatt, 1970; Teleki, 1975; Garber, 1987; Domínguez-Rodrigo, 2002).

Scavenging, Hunting/Gathering, Fire, and Cooking

Studies of free-ranging primates (baboons) confirm that when meat, animal products, and insects are available for consumption, these items are preferred over available plant foods (Hamilton *et al.*, 1978; Hamilton and Busse, 1978). In contrast, studies of contemporary human hunting-gathering bands suggest that earliest hominid societies would have formed food patterns that contained reasonably balanced quantities of wild plants and animal products (Lee, 1979; Lee and DeVore, 1968). This dichotomy – meat versus plant-based patterns – poses an enigma because the majority of wild plants growing in any ecological niche potentially are toxic to humans (Leopold and Ardrey, 1972a, 1972b). Foraging through the bush to collect plant food resources, whether berries/fruits, leaves, nuts/seeds, or tubers, would not have been simply making selections from wild food offerings. The African savannah where humans evolved would have represented an environment where most ancient (as well as recent humans) had to resolve a basic issue: how to identify consumables safe to eat so not to be poisoned by bush plants.

One key to solving the safe versus toxic plant problem was advanced in the early 1970s. The argument posed was that the ability to make and maintain fire led to cooking and cooking, in turn, rendered a significant suite of available plants and plant products safe to consume (Leopold and Ardrey, 1972a, 1972b). Cooking plant foods would have improved the survivability of these early consumers because enzyme inhibitors in legumes and cereals would be denatured; physiological irritants such as saponins as well as lathyrogens, irritant oils, and cyanogenic compounds reduced or neutralized; some allergens would have been deactivated; and compounds that interfered with hominid hormonal systems, goiter-producing compounds, and vitamin and amino acid antagonists also would have been reduced (Leopold and Ardrey, 1972a, 1972b). Cooking also would have improved digestibility of plants, the bioavailability of nutrients, and caloric value of cooked foods would have been increased compared to raw foods (Wrangham and Carmody, 2010; Carmody *et al.*, 2011).

Yet early hominids and human hunter-gatherer populations lived without benefit of fire and cooked foods for most of their existence. Earliest archeological evidence for the ability of hominids to make, maintain, and use fire is highly variable by global geographical region: dated to 300–400 000 BP in Europe (Roebroeks and Villa, 2011); 790 000 BP in the Middle East (Goren-Inbar *et al.*, 2004; and c. 1 000 000 BP in Northern Cape Province, South Africa (Berna *et al.*, 2012).

Food Safety

For the vast majority of time early hominids and humans existed they did so without the benefit of regular cooking fires. Throughout this lengthy time period hunting-gathering groups had to determine what was safe to eat. One consideration could have been to focus on wild plant products that were sweet and to reject bitter items. Still, some sweet plant products (berries, leaves, roots) can be toxic, and some bitter plants/plant parts can be safe to consume.

Regarding meat and animal products earliest hominids and humans would have been scavengers and only rarely would have killed large game (Shipman, 1983). They would have consumed smaller animals, scavenged carrion, and eaten the digestive stomach contents of animals previously killed by predators. Scavenging from kills made by larger savannah predators, hunting smaller game, gleaning berries and fruits, nuts, and pods, and digging for and washing/stripping tubers would have presented options that were either safe or toxic to consume. Identifying what was safe to consume in a specific environmental niche remained the first problem that had to be solved, one that has continued into historic times as well. If food safety was learned only through basic trial and error, then untold numbers of hunting-gathering band members would have died periodically because of toxic plant poisoning.

In solving this problem early hominids might have observed what birds or mammals ate and followed such patterns? Eating carrion from fresh or older kills made by carnivorous predators also could have been an early hominid food pattern. (Although Jewish, Christian, and Muslim religious texts decry and condemn the consumption of carrion, the baTlokwa ba Moshaweng of southeastern Botswana have no taboos against the practice and regularly practiced carrion consumption (Grivetti, 1976). Some minority societies in Europe regularly have feasted on carrion (Petrovic, 1939).) William Hamilton and his research team studied free-ranging baboons in the Okavango region of northern Botswana and reported that members of the troop ate widely across the available plant spectrum, consumed large quantities of ripe and unripe fruits, dug for tubers, and stripped and ate a broad range of grass

seeds (Hamilton *et al.*, 1978). These baboons, however, regularly vomited as they foraged for food. Further, they ate large quantities of clay throughout the day (Hamilton, personal communication, 1990). Such a pattern of eating clay along with wild bush plants could have been an unconscious mechanism that protected these hominid consumers. Given that the practice (geophagia) can lessen the absorption and physiological effects of certain categories of plant toxins (Halstead, 1968). Further, contemporary studies document that if consumers vomit after eating, this result can lead to future rejection of the offending products (Garb and Stunkard, 1974; Stockhorst *et al.*, 2006). Perhaps through such methods and through basic trial and error, the hominid consumers could have learned and ultimately differentiated between 'safe' and 'toxic.'

Determination of food safety might also have come about through potential 'selective filters' consciously or unconsciously that led earliest hominids and early humans to initially identify and repeat consumption of safe foods. Although dogs were domesticated c. 30 000 BP canines have served more recent hunter-gatherers to determine which bush plants are safe to consume. The Gwembe Tonga of southern Africa, a contemporary agro-pastoral-hunting-gathering society, allow their children to forage in bush lands without adult supervision where they search for and experiment with different plants as potential foods. When a questionable species is encountered, presumed edible portions initially are fed to their companion dogs. The children observe the canine's behavior and after a reasonable period of time – if the dogs do not vomit and survive – then the adventurous children may taste and eat the new plant (Scudder, 1971).

Might human 'tasters' also have been used in early antiquity to test the safety of new plants or suspicious items? Could they have been adults captured from rival bands; perhaps women beyond childbearing years; aged men who had lost their hunting acuity; or perhaps the sick or the infirm? (The third century Egyptian-Greek writer Athenaeus addressed the issue of the ancients using elderly women as food tasters (Athenaeus, IV:172:A) and regular reports document that Southeast Asian immigrants to the US have been poisoned after incautious foraging and consuming what they believed to be species safe to eat (Fischer, n.d.).) Although such suggestions pose moral and ethical considerations when examined through contemporary twenty-first century prisms, would such cultural niceties have characterized earliest hunting-gathering groups?

Learning the safe plant foods in one niche, however, would not necessarily extend safety into other ecological zones, as the botanical assemblages might contain items that only appeared similar to safe items. Identical species that grow in two different environmental niches can pose problems: plants safe to eat in one ecological zone, but poisonous in another niche, are called 'toxic analogs.' Toxic analogs look nearly identical to species already accepted as safe foods and illness and/or death from such plants has remained a perpetual problem facing hunting-gathering groups in antiquity and sometimes even modern societies today (Gadd *et al.*, 1962; Scudder, 1971; Beug, 2005).

Ultimately hunting-gathering bands would have expanded their territorial ranges leaving the warm, moist tropical regions of eastern Africa to explore and exploit more temperate and colder climes and ultimately extended the early human geographical range into global subarctic and arctic zones. In addition, consider massive human movements such as the peopling of the Americas, crossing the Bering Sea land bridge, and how hunting-gathering bands worked their way southward toward the equator – eating along the way. Recent evidence suggests that the people of the Americas occurred in multiple pulses from Asia and possibly from Europe (Bradley and Stanford, 2004; Fagundes *et al.*, 2008). Moving from north to south through what is now Alaska to what is now southern Chile, many dozens of ecological zones would have been negotiated and food safety issues solved. From twenty-first century vantage points we may only speculate how safety was learned and transmitted throughout the millennia.

Nutritional Balance and Competitive Foraging Strategies

As the food safety issue was solved, there remained issues of dietary adequacy and overall nutritional balance. If ancient hunter-gatherers subsisted on a diet that was deficient in energy, protein, or essential vitamins or minerals, the group would languish; individuals would become weak or ill; and either would have succumbed directly to dietary imbalance or easily predated (Speth and Spielmann, 1983; Speth, 1987). Countering this 'survival of the fittest' view is one suggested since the 1920s that humans (infants) instinctively know what to eat and how to balance their food intake patterns and diet (Davis, 1928, 1939). By extension some have speculated that early humans might have exhibited an inborn mechanism that assured dietary balance. Most nutritionists today, however, reject this view because careful examination of the 'self-selection' research conducted in the 1920–30s does not support this contention (Story and Brown, 1987). Early hominid and human consumers could not have determined or known what constituted a physiologically or nutritionally balanced diet: there is no 'felt need' for protein or for specific vitamins or mineral. The problem would have been solved, therefore, through natural selection: good food intake patterns would have evolved through trial and error; those hominids and early humans with sound patterns survived and reproduced; those who made poor food intake choices did not. Contemporary hunter-gatherer bands in the Kalahari Desert of southern Africa, for example, have continued to exhibit basic good health and overall sound nutrition without the aid of twentieth or twenty-first century theories (Truswell and Hansen, 1968; Truswell, 1977).

Competitive foraging strategy analysis has been used by behaviorists (ethologists) to investigate and categorize the food patterns, band movements, and interanimal activities. Among free-ranging primate troops, males and females with highest status (identified as Alphas) enter prospective plant zones to forage for food; troop members with lower status remain along the periphery and wait until the Alphas have finished eating before entering the zones. During their time in the food zones, the Alphas will have stripped and gleaned most of the edible foods leaving behind less favored items. Those lowest in troop social status (identified as Omegas) remain along the periphery for longest periods of time and

invade the food resource areas only after the Alphas have eaten and moved on to other localities. Time is a great enemy to the Omegas because lingering along the periphery presents greater risk through predation. In addition, the Omegas who eat last from the residual food resources experience reduced food selection opportunities and potential dietary imbalance. Poor diets through time lead to malnutrition: the Omegas then become weak, eventually ill, and are easily predated. The well-fed Alphas continue their lives, mate with the best females and reproduce, and the band survives. This natural selection process could result in sustained and potentially repeated food patterns by the Alphas who if their food intake patterns were balanced nutritionally, the pattern could continue into the next generation. In contrast, the Omegas gradually would vanish as the strong survived (Pyke *et al*., 1977; Hladik, 1981).

Just being an Alpha, however, does not assure that the knowledge of what is safe and not safe to consume is transmitted to other troop members or to subsequent generations because food sharing among most nonhuman primates has not been observed. William Hamilton's team of primate researchers working in the Okavango region of northern Botswana never recorded instances where adult male or female baboons picked, dug, or striped plants and then shared the food items with other adults, juveniles, or infants. (Hamilton personal communications, 1985–90). Sanford Harcourt working among gorillas in Rwanda, never recorded that these great apes offered or shared food with adults or juveniles (Harcourt, personal communication, 2013). One general explanation for this 'personalized egocentric' behavior has to do with limited brain development and intelligence, which sets early hominids apart from early humans. Still, food-sharing behavior among other nonhuman primates has been reported, specifically by chimpanzees, douc monkeys, and gibbons (Kavanagh, 1972).

Could it be that food safety and ultimately dietary balance was transmitted to infants through observation and mimicking what their mothers had consumed, or perhaps infants nuzzling adult females to obtain scents of foods just eaten? However, given that free-ranging primates and early humans ate broadly and widely across the spectrum of available plant and animal items, it seems likely that dietary and nutritional balance came about through natural selection and survival-of-the-fittest processes – provided they were not poisoned.

Food Security

Through the millennia hunting-gathering bands ultimately solved these food safety and nutritional balance problems. Having enough to eat, however, during wet and dry seasons within the tropics and during colder/warmer periods when bands ranged outside the tropics, remained still another problem. So long as band size remained small (c. 30–40 individuals), 'adjustment equilibriums' would have evolved where foraging/hunting did not outstrip the available food resources in specific occupation regions.

Food storage, however, would require a formidable conscious decision, given the ease of hunting-gathering through well-traveled ecological zones familiar to the band. Amassing a large quantity of gathered foods would make little sense to hunter-gatherers conditioned to a pattern of hunting-gathering their food needs on a regular basis. Yet, what if through trial and error some groups discovered that left over grain could be fermented to produce a mind-altering beverage? The possibility then could be that some band members might make conscious decisions to gather grain in excess, develop pits for storage, and convert a portion into beer (Katz and Voigt, 1987).

Plant Selection and Incipient Cultivation

Study of contemporary hunter-gatherer societies during the past 150 years has revealed that they exhibit wide knowledge of plant availability and uses for esthetic decorative items, clothing, cooking devices, cosmetics, dye, fiber, food, medicine, poisons, toys, weapons, and other utilitarian needs. Some plants merely would have been gathered; others dug up, harvested, or berries, nuts, seeds, or tubers collected and some of these could have been planted adjacent to hunting-gathering encampments. Such could be the case where shamans gathered and transplanted medicinal and/or ritual species to have more easy access. The present author observed this practice when working among the baTlokwa ba Moshaweng in the eastern Kalahari Desert of modern Botswana – where medicinal species had been planted adjacent to homesteads of traditional healers that had continued to flourish long after the sites had been abandoned. Such limited planting without tending or cultivation is not agriculture, *per se*. The present author also observed that the baTlokwa also regularly dug up more than 50 wild bush species and transplanted them in their settlement compounds: only five of these species, however, served as food and the vast majority provided social/cultural needs for esthetics (attractive blooms), dye, fiber, medicine, and magical/protective charms (Grivetti, 1976).

Human Settlement and Development of Agriculture

Settlement and the subsequent development of agriculture radically changed forever human societies. Agriculture in the strict sense cannot predate human settlement. Planted gardens/fields need to be watered, tended, and protected lest mature plants be stripped by wild animals or competing rival human groups. Questions where and why settlement initially occurred, as well as how and why incipient planting and agriculture developed, have been debated by anthropologists, botanists, geographers, and others for more than a century (Ucko and Dimbleby, 1969; Isaac, 1970; Gepts, 2004; Grivetti, 2004).

Settlement also reflects individual or collective decisions whether or not to continue hunting and gathering, whether or not to remain mobile during portions of the year, or to take the drastic economic step and become sedentary. It is reasonable that early settlers could do so only in the midst of wild plant food abundance, where the initial 'settlement' might be perceived as a central node where band members not only could initiate the process of growing plants for food and other needs, but also hunt and gather in different directions (perhaps up and down slope if settled in a highland region) which would allow selections from within a highly diversified range of plant resources. Such clan-based decisions to become

sedentary also would require stable and reliable water resources, perhaps adjacent to lakes or rivers. Other potential areas for settlement could have been near oceanic shores where clan members could take advantage of intertidal organisms, hunt marine mammals, and fish, and augment their diets by gathering plants (Braidwood, 1960; Sauer, 1969; Sauer, 1972).

Initial settlements, however, need not have been stable or have led to incipient planting. Within bands of hunter-gatherers, there could have been individual and/or collective decisions to settle based on specific nonfood needs: perhaps illness/infirmity of key band members could have led to temporary year around or seasonal settlements where the annual round of activities would have been abandoned until the group decided to move on as before. Small groups within larger bands of hunter-gatherers might have elected to stay at a localized camp, but for such a group to flourish both genders would be represented, especially women of childbearing age. Such early settlements would require joint decisions how to protect against predator animals and/or against potential raiders from competitive bands.

As decisions to settle were made a suite of potential problems unrelated to incipient planting and ultimately to agriculture would have occurred. Earliest settlements would experience increased populations and a complementary rise in population density and a corresponding higher risk for illness and disease caused by more frequent human-to-human contact, coupled with probable contamination of water resources (Heizer, 1978). Intensive gathering would have continued in lands adjacent to these early settlements, and as locally available food resources became in short supply the adjustment equilibrium would change dramatically requiring further and further treks into the bush to obtain wild food resources.

There then could come a time when it became obvious to certain settled band members that seeds or roots of preferred species could be planted near the settlements to stabilize the food supply and meet other utilitarian needs whether for dye, fiber, medicine, perhaps religious uses. Such incipient planting activities would reduce the need for longer treks into the bush for game and wild plants. The process of selecting utilitarian plants to grow already would have been in place, and as culling practices altered gene pools and the species grown became distinct from their wild progenitors, the process of plant domestication would be achieved (Helbaek, 1959; Ucko and Dimbleby, 1969; Isaac, 1970; Cowan and Watson, 1992; Gepts, 2004).

Earliest Agriculture: Theories and Constructs

Some have suggested that the transition from hunting-gathering livelihoods to settlement, to incipient cultivation, and to agriculture were lengthy processes. These processes while lengthy could have been facilitated by observational behaviors that ultimately resulted in cultivation.

Predisposing Factors

The argument has been advanced that hunter-gatherers must be predisposed to perceive the potential value of incipient cultivation. Predisposed in this context would be similar to the case where Alexander Fleming recognized the importance and implications of the contamination of his agar-plated laboratory dishes and the 'ring of inhibition' that ultimately led to the recognition and isolation of penicillin – because he was 'predisposed' to consider why the 'ring of inhibition' was present (Macfarlane, 1984). Two predisposing factors have been advanced as processes that could have led early hunter-gatherers to perceive that certain wild plants might be grown near their campsites. At the core of both is the notion that before incipient cultivation and formal agriculture could be implemented, wild plants with potential food or other utilitarian uses first had to be brought into a proximal relationship with hunter-gatherer encampments.

Animals as seed concentrators

Through digestion and excretory processes wild animals and subsequently domesticated animals serve as selective filters as they graze through the plant kingdom. The berries, fruits, and seeds consumed ultimately fit two categories: items totally digested, and those where the partially digested seeds remain viable in animal feces. Although not tempting from twenty-first century perspectives, the feces of many wild herbivores – and domesticated mammals as well – may be harvested for human food through 'fecal gleaning,' where animal droppings are examined for undigested seeds that could also serve as human food. The baTlokwa ba Moshaweng of the eastern Kalahari Desert feed fruits of *Sclerocarya kaffra* to their goats; the goats digest the soft outer pulp, while the kernels pass out with the feces. These 'goat-gut treated' nuts subsequently are collected, washed, dried, and consumed by women as special dietary treats during pregnancy (Grivetti, 1976).

Goats from the baTlokwa family herds are let out from their pens in the morning to forage widely within adjacent bush lands then are re-penned at night. During the dry season dung accumulates in the goat *kraals* and so long as the goats remained penned, any seeds that might be viable cannot sprout or grow because of repetitive hoof actions. With the arrival of seasonal rains the goat *kraal* floors become sloppy; coats of the goats are washed; and the animals removed and penned in newly constructed *kraals*. The seed-rich nitrogenous ground inside the abandoned *kraals* then burst forth with new growth and so-called 'goat-*kraal* garden' are created. Young girls then are sent to inspect the previously abandoned goat *kraals* and report whether or not useful plants are present. If so, these areas are re-fenced with acacia branches and the enclosures treated, collectively, as family properties for harvesting (Grivetti, 1976; Grivetti, 1980).

The goats in this baTlokwa system acted as 'selective filters' and brought a spectrum of plants into proximal relationships with humans. Given that goats may be among the earliest animals to be domesticated, and that animal domestication preceded agriculture (Reed, 1959), might it have been that animals serving as seed concentrators contributed to incipient cultivation and eventually to the development of agriculture?

Humans as seed concentrators

The thesis proposed by Edgar Anderson known as the 'garbage dump hypothesis' also casts light on potential incipient cultivation, earliest agriculture and plant domestication.

Hunter-gatherer bands establish temporary camps at well-defined locations during their annual round of activities that are revisited during subsequent periods. Such groups keep their camps relatively clean of garbage and human excreta so their 'garbage dumps' are located along the periphery of these temporary camps. After hunting-gathering groups have returned to an earlier encampment, one of the initial activities is to inspect the peripheral 'garbage dump' for possible utilitarian uses. Growing from such sites are seeds that germinated from discarded food and human excreta. Anderson suggested that if certain individuals in the hunting bands were predisposed to and perceived the utilitarian value of such garbage dumps, it would not be a difficult leap forward to the idea of transplanting favorite plant species – and incipient cultivation would result (Anderson, 1952; Hughes *et al.*, 2007).

Purposeful Constructs

Some scholars have argued that the development of agriculture was driven by specific human need-based decisions, considerations sometimes called economic or purposeful views or constructs.

Sudden insight

Some fiction writers have suggested that stone-age persons – men or women – suddenly developed the brilliant idea: let us go out and start raising beans or grains – for whatever purpose. The thesis advanced suggests that some individuals became tired of their nomadic existence and perpetual roaming in the quest for game and wild plants. This thesis, in one form or another, has appeared in popular literature (cf. Michener, 1965). Sudden insight – also called the 'good idea' concept – commonly is articulated like this:

> I'm tired of walking long distances and spending most waking hours looking for food; let us settle and not follow the herds of wild game; after we settle we can plant wild foods near our encampment and when the plants grow we will have all the food we need.

Could be that individuals just decided to settle because they were tired? Or perhaps some groups settled because band leaders (Alphas) were injured and unable to travel with the remainder of the band? Regardless of motivation early bands would have done so in the midst of food plenty among plant species already known and consumed.

Hunger and necessity

The oft spoken adage 'necessity is the mother of invention' sometimes has been applied to understanding settlement and the development of agriculture. Some have argued that agriculture came about because of the need to incessant hunger or to offset famine. The argument goes that continued hunger drove early hunter-gatherers to develop their stable food supply through agriculture (Cohen, 1977).

Hunger and famine, however, need not lead to planting and agriculture because there is not enough time for the solution to solve the need. Evidence from recent centuries demonstrates that individuals and families either cope with famine – or die. Further, hunger strike survival rates reveal that most adult individuals – if already well-fed, in good health and with access to water – can exist without food only for 40–60 days (Collins, 1986; Rodriguez *et al.*, 1993). During periods of extended food deprivation individuals become lethargic and have little energy for cultivation and agricultural pursuits (Richards, 1932; Keys, 1950; Matalas and Grivetti, 2007).

Environmental desiccation

Some scholars have argued that during periods of major climatic change and drought, environmental desiccation drove humans and animals into riverine environments. such as valleys of the Nile, Tigris-Euphrates, Indus, and Yangtze (Childe, 1936, 1951). It is argued that once inside these well-watered river zones, humans and animals competed for space, food, and water needs, and the development of agriculture and domestication of plants were the results of these interactions brought about by proximity (Braidwood, 1960).

River valleys could offer safe-havens for hunting-gathering bands searching during drought for stable water supplies. But river valleys flood periodically and without the skills to manage water, annual flooding would be a constant challenge to early hunter-gatherers and/or early settlers if attempting to cultivate. Still, living in population-dense river valleys would have forced people together with animals and plants; herds then would have been culled and the botanical array extensively harvested and selected for specific traits. Perhaps some plants and animals were easier than others to work with, to transplant, to tame, or to manage? Evidence from ancient Egyptian tomb art depicts historical attempts to tame and perhaps domesticate ibex and hyena. But attempts with these animals were not successful and were abandoned. Thus, mere proximity to specific plants and/or animals may or may not have led to the development of agriculture or to animal domestication (Darby *et al.*, 1977).

Population pressure/density

One popular thesis holds that the need for humans to eat and to maintain a stable food supply ultimately led to domestication and agriculture. In this instance the 'necessity' was pressure for land or space. Proponents of this theory claim that the prime mover was population density, where increased population pressure on a given landscape area offering edible wild plants, ultimately forced humans to settle and raise crops. The explanation offered considers there were simply too many people around settlement campfires, too many mouths to feed, so population pressure/density and the need to feed more individuals ultimately led to agriculture (Cohen, 1977).

Degenerate hunters

At the heart of the degenerate hunter thesis – sometimes called the 'poor shot' or 'beer-brewing thesis' – is the view that the best hunters in early hunter-gatherer groups ultimately became discouraged with the poor hunting skills of others in the band. The argument follows that hunting bands split: excellent hunters went in one direction, whereas those with poor hunting skills remained behind and settled in locations with abundant wild cereals. The thesis holds that through a long process some band members learned to ferment quantities of excess wild grain into beer. Because each band would be composed of both excellent and poor hunters, it could have come about that the best hunters ultimately became

discouraged in having to share meat with those band units unable to 'do their fair share.' Proponents of the degenerate hunter thesis argue that the best hunters made decisions with far-reaching implications:

> You no longer will hunt; you and your women remain in camp and gather wild grains; we will continue as before and hunt; we will supply you with meat – you will provide us with beer.

And the theory contends that from this dichotomy the degenerate hunters tended and protected stands of wild barley and wheat and from these harvesting/culling actions grains agriculture and domestication evolved (Katz and Voigt, 1987).

This thesis suggests, too, that agriculture ultimately develop because early humans initially sought plants for their mind-altering, drug-inducing capabilities. Plants containing seeds that could be sprouted and fermented would have been favored over others and used for production of alcoholic beverages. Proponents suggest that it was the discovery of alcoholic stupor and desire to experience repeated intoxication that was the impetus for cereal agriculture and ultimately – settlements, villages, towns, and technological advances made by settled peoples – whereas the best hunters continued in their annual rounds of activities, did not domesticate, develop agriculture, or achieve technological benefits.

Contemporary studies of hunting-gathering groups, however, provide insights on processes whereby individuals with disparate hunting skills remain associated with the same bands. The !Kung Bushmen of the northwestern Kalahari Desert practice two such behaviors that keep the best hunters from 'hiving-off,' taking women and leaving less gifted hunters to their 'agricultural' fate. One such mechanism is that !Kung hunting arrows carry specific markings that identify their owners; before leaving camp, the men share arrows in a manner that the quivers of the best hunters contain arrows belonging to others who may be 'poor shots.' When an elite hunter kills a large beast he is required to share half the meat with the owner of the arrow used to kill the animal, a process that assures that meat is shared among the various band members and not just within the immediate family unit of the best hunter. The second behavior occurs when one of the best hunters kills an animal: other hunters subsequently deprecate his skills and heap scorn on him, saying 'lucky shot' and other derisive comments. Arrow trading and such comments serve the function of reducing egotism among the best hunters – so the 'good shots' do not become self-centered and decide to leave (Marshall, 1957; Lee and DeVore, 1968; Lee, 1969; Lee, 1979).

Unconscious Constructs

Still other scholars reject such economic or purposeful factors and hold that the development of agriculture had no 'prime motivations.'

Intimate knowledge

This thesis holds that during the process of managing everyday life humans unconsciously alter their environmental setting. Early humans readily utilized both plants and animals whether for food or other purposes. In doing so humans gained an intimate knowledge of the local flora and fauna for different purposes whether for dye, fiber, food, medicine, mind altering drugs, toxins for arrow poisons, and perhaps religious uses. In gathering these species and ultimately practicing incipient planting adjacent to campsites, the environmental setting and gene pools unconsciously were altered and the process leading to domestication was accelerated (Anderson, 1952; Sauer, 1969; Sauer, 1972).

Mutual domestication

The theory holds that human gathering of wild plants never would have been random because examples gathered would have been selected for a range of needs and impulses, of which use as human food was merely one. Massive and long-term culling of stands of wild plant species ultimately produced a genetic shift away from the wild progenitor. It has been argued that both plants and humans produced evolutionary changes in both directions: that human physiology changed as domestication of carbohydrate-rich plant foods advanced and plants changed and became codependent on humans and in some instances such as maize, required human involvement and supervision for propagation (Rindos, 1984).

Agriculture-Domestication Enigma Revisited

Scholars have examined and debated preconditions and the various agriculture and plant domestication theories for many decades. Within these debates four basic issues for consideration have remained.

Why Settle?

Before the development of agriculture, all people lived as hunter-gatherers. Hunter-gatherer are not settled and move in well-defined annual routes during their annual round of activities, and move through broad territorial ranges in search of game and plant foods. Agriculture, in contrast, requires a settled lifestyle, a social-economic pattern divorced and unrelated to the previous lifestyle where hunter-gatherers migrated in search of food.

Carl Sauer argued that agriculture developed among 'sophisticated fishing societies,' groups of hunter-gatherers already settled along the shores of highland lakes, or perhaps along coastal strips where they fished, hunted, and collected plants (Sauer, 1969, 1972). Solomon Katz suggested that settlement and first agriculture evolved, instead, from 'gatherer groups' left behind by better hunters where the prime motivation for settlement was the preparation of intoxicating beverages (Katz and Voigt, 1987). Both arguments place earliest settlements in zones of wild plant abundance and diversity. The Katz thesis placed earliest settlers in the midst of food plenty where they subsequently adopted a sedentary lifestyle. The Sauer thesis considered that the bands already were settled but continued to hunt and gather up and down slope to obtain plants for utilitarian purposes. But with ample supplies of fish and/or other animals for hunting, coupled with and an already rich plant food base, why would such groups start to grow plants given the available species diversity?

Why Settle in the Midst of Plenty?

Nikolai Vavilov the Soviet botanist and plant geneticist developed a widely considered thesis that has served as one of the foundation stones for the discussion of early agriculture and plant domestication. Vavilov argued that geographical locations that exhibited the highest hybrid diversity were the earliest locations for agriculture: most hybrids – most ancient agriculture and domestication. What became known as Vavilov's 'Centers of Diversity' were distributed geographically within Africa, the Americas, Asia, and Europe (Vavilov, 1949). The Vavilov center concept continues to present students of agricultural origins with a basic problem: why would hunter-gather societies settle and cultivate food plants in the midst of geographical zones of wild food plenty?

Jack Harlan traveled to southeastern Turkey/northwestern Syria – and conducted a simple experiment. This was the earliest geographical location where Vavilov argued that barley/wheat had been domesticated and cultivated based on highest frequencies of hybrids. Harlan took a primitive flint tool and started harvesting wild wheat. In a very short time he had obtained enough wild grain that could have fed a family of hungry hunters-gatherers for several weeks: with such conditions and ease of collection, why would settlements and agriculture develop (Harlan, 1967)?

Harlan concluded there would be no pressure to settle or ultimately develop agriculture: and offered a counter proposal, one he called 'The Noncenter Thesis.' He suggested that settlement and earliest agriculture would have taken place along the peripheries of the Vavilov 'Centers,' in geographical areas that provided the impetus for initial incipient planting and ultimately the development of a stable food supply (Harlan, 1971).

The 'Center' versus 'Noncenter' debate continues: those who support Vavilov must provide solutions to the question why hunter-gatherers would develop agriculture in the midst of such wild food abundance. Those who support Harlan must answer why agriculture would develop at the periphery of the 'centers' where the archeological evidence remains controversial.

Why Domesticate Toxic Plants?

A third controversial supposition suggests that in some geographical areas earliest cultivation and domestication was not for food but was driven by utilitarian needs for plants that could be processed for their toxins and used to kill fish or other game. Such an example of a toxic plant that ultimately can serve as a human food resource is manioc or cassava (*Manihot esculenta*).

Manioc was domesticated and initially cultivated in tropical South America in the Amazon basin perhaps 10 000 BP (Olsen and Schaal, 1999). Manioc roots contain significant quantities of cyanide, must be processed, and the poison eliminated before the starchy residue is suitable for human consumption. How would it be possible to recognize that a poisonous plant could serve as a potential food resource without first developing the technology to render it safe for human consumption? The only logical conclusion to be drawn is that manioc initially was selected, cultivated, and ultimately domesticated for its toxic properties before recognition that after processing it could serve as a food resource.

More than 50 years ago the botanist Edgar Anderson proposed that food was not the primary rationale behind plant selection and ultimate domestication. He suggested that plants were domesticated and cultivated because of their esthetics, beauty, color, and other nonnutritional reasons (Anderson, 1952). Through the ensuing decades Anderson's thesis has not found fertile ground among many agricultural scientists, especially those who believed and echoed the viewpoint that food was the primary driving reason/force behind domestication and the development of agriculture. But consider Anderson's thesis, especially in light of the domestication of manioc, and how by stripping away the concept that food was the rationale for early agriculture and domestication, how this toxic food ultimately became a dietary staple, through a process that might be called 'the-child-who-did-not-die' thesis (Susan Birch, an undergraduate student at the University of California, Davis, may have been the first to coin the 'child-who-did-not-die-thesis' when she suggested that manioc initially had not been domesticated for food, but as a fish toxin; the processed mash would have been discarded and not perceived suitable as human food – until accidental consumption of the processed mash by a child – who did not die. Simple and parsimonious!):

> In the central Amazon region an early cultivator pounded and pressed cassava/manioc to extract fluids used to kill fish; doing so the starchy pulp was discarded. An unsupervised child wandered by, reached out and stuck a handful of still damp cyanide-extracted mash into its mouth. The adult watched horrified but was too slow to respond. The child smiled, survived, and the adult made the association that cassava mash was not poisonous; the adult tasted the mash and found it bland but pleasing.

This 'child-who-did-not-die' thesis also could apply to other human foods, for example, acorns and cycads that initially are toxic and require extensive processing before human consumption.

Adverse Dietary Impact

Once agriculture and domestication occurred, the dietary diversification of items that formed human food patterns decreased. Reduction in dietary diversity and a focus on carbohydrate-rich grains and tubers produced radical changes and impacts on the overall composition of human diet that ultimately resulted in major physiological changes. Accompanying the development of agriculture and plant domestication human stature decreased and human cranial capacity declined. These reductions seen in the archeological record were caused in part by higher intakes of cultivated plant foods and lower meat consumption. Is it not curious that Mesolithic European hunters c. 20 000 BCE were taller and had larger brains than their c. 10 000 BCE settled Neolithic European plant-raising counterparts? The same patterns are seen when analyzing skeletons buried at sites before and after maize domestication in the New World (Newman, 1975; Cohen and Armelagos, 1984; Larsen, 1995).

All studies of contemporary, traditional hunting and gathering societies reveal high dietary diversities. In some

instances more than 300 different animals and plants regularly are consumed annually (Grivetti, 1976). Further, studies conducted in Botswana by Barbara Metz compared food patterns of hunter-gatherers, pastoralists, and agriculturists that occupied the same general geographical territory and ecological niche in northwestern Botswana. The !Kung hunter-gatherers included in her studies exhibited better overall nutrition and health status than either the Herero cattle pastoralists or the baTawana agriculturists who occupied the same niche, whereas the health-nutritional status of Herero pastoralists was superior to that exhibited the settled baTawana farmers whose diet was based primarily on sorghum augmented with plant relishes (Metz *et al.*, 1971).

It is axiomatic among nutritionists that the best practices to assure quality diet is to expand dietary diversity – not reduce the number of foods consumed. But with the development of agriculture and animal husbandry, and with subsequent domestication of animals and plants, human dietary diversity decreased sharply, a factor that presents an interesting counterpoint to the principles on which dietary security in the twenty-first century are based.

Agriculture, Domestication, and Future Food Security

Regardless of debates why early humans settled, developed agriculture, and ultimately domesticated plants, agriculture stabilized human food supply and expanded food production not possible merely through hunting-gathering activities. Given the broad diversity of potential plants that could be domesticated, researchers have debated why humans focused on specific categories of plants, whether food or nonfood items, and if for food, were the choices dictated primarily for caloric energy or for protein content (Lechler, 1944; Dart, 1963; Gaulin and Konner, 1977; Isaac and Crader, 1981; Peters and O'Brien, 1981; Stahl, 1984; Eaton and Konner, 1985).

After human settlement and the development of agriculture there followed a general reduction in the variety and numbers of plant foods consumed. Today in the twenty-first century the number of known plant species is c. 400 000 (Botanic Gardens Conservation International, n.d.). Of this number, however, only a small minority contribute 90% of all carbohydrate calories consumed globally, among them: barley, cassava/manioc, maize, millet, potato, rice, rye, sorghum, sugarcane, sweet potato, taro, wheat, and yam. This pattern of reduced food diversity exhibited by advanced agricultural and urban societies in the twenty-first century differs sharply from food intake approaches followed by hunting-gathering societies who because of remote antiquity have eaten broadly across the spectrum of both plant and animal kingdoms.

Agriculture as practiced today by traditional societies in the Americas, Asia, Africa, and Oceania is represented by fields that appear 'jumbled,' where many types and varieties of plants are grown within the same plots. Throughout traditional fields in Mexico and Central America maize, beans and squash are planted together. Maize extracts nitrogen from the earth, whereas beans being nitrogen-fixing, replenish soil fertility. The maize stalks serve as 'beanpoles,' and the broad leaves of the interspersed squash plants shade the earth and reduce evaporation. Such a sustainable agricultural pattern does not lend itself to mechanical harvesting. In Africa traditional household gardens and small cultivated fields may contain 20 or more different plant species, including both domesticated and wild plants that represent both food and nonfood uses. Such convoluted, mixed gardens and fields appear in sharp contrast to the vast fields of grain or other plants grown under near monoculture conditions in more economically developed regions of the world. These large primarily single-crop fields lend themselves to mechanical harvesting, whereas the 'messy' traditional fields do not. Because both approaches to agriculture are practiced globally, a question may be posed: which pattern presents a more secure food base for current and future human consumers?

What if an unusual plant virus, a mold, rust, or smut, attacked the botanical spectrum of cereals cultivated today in 2013 and caused a 20%, 50%, 75% reduction of cereal yields for just one year? What would be the worldwide economic and social impact? What economic, political, military, and moral-ethical problems would follow such a collapse of the global grain distribution system? What decisions to alleviate local, regional, and national food shortages would be taken by responsible leaders of government, industry, and academia? Could the economic and human chaos sure to follow under such a condition be averted? What would be the impacts if such a disaster were to occur in 2020; within the next 20 years; perhaps during the year 2050?

More than 50 years ago John Christopher wrote a chilling novel, entitled *No Blade of Grass*. His thesis set within the classic doomsday genre of the Cold War was published during an era of press scenarios of a global population crisis and Malthusian future, raising doubts on the abilities of poverty-stricken countries to feed and maintain their expanding citizens through the so-called Green Revolution and beyond. The central thesis of Christopher's novel was that a virus suddenly appeared that attacked rice and eliminated the dietary staple of Asia. In Christopher's fictional account 200 million Chinese suffered famine and starved, followed by the collapse of rice-consuming nations in southeast and south Asia. And as scientists rushed to halt the spread of the rice-specific virus and to restabilize world food supplies, the virus mutated and infected all wild and domesticated grasses: barley, maize, millet, oats, rye, sorghum, wheat, and even sugarcane. Although the dietary-food catastrophe initially was limited essentially to Asia, the loss of domesticated cereals progressed quickly to Africa, then the Americas and Europe (Christopher, 1956).

We in the twenty-first century should not smile smugly and reject the basic premise on which Christopher's novel was based – an attack on the global food supply by a fungus, virus, or other organism – because such an event would produce unthinkable consequences. One measure of the importance and potential impact that such a disaster would have on human food resources is to examine what actually happened in the late 1960s and early 1970s when many American farmers lost their entire maize crop because of blight (Cordain, 1999).

But what were the ripple effects from the loss of the maize crop in this more localized agricultural catastrophe? Consider how maize – then and now – continues to be interwoven

through the international food and grain markets whether in the 1970s or in 2013, or 2050: as a source of human food, cooking oil; petrol; sweeteners; chicken and hog feed; and nonedible commercial products even dusting powder used to keep paper cups from sticking together.

What lessons should be learned from this maize near catastrophe? One lesson is how potentially precarious global food markets are in a complicated, technical world. As agriculture has moved toward fewer and fewer varieties under cultivation agricultural practices of the last century have tended more toward monoculture in order to facilitate mechanical harvesting, with a parallel loss of genetic diversity in the types of domesticated products grown. As a result, has the human agricultural food supply become more secure or less secure because of changes in cultivation systems during the past 10 000 years?

Do modern humans have greater food security than their ancient or contemporary hunter-gatherer societies? Will the global food supply be more (or less) secure in 2050 and beyond as a result of plant domestication and current agricultural practices? Finally, let us ponder the questions posed at the onset of this essay regarding the early human quest for food, how food safety issues were solved, and the rationales behind human settlement, plant domestication, and development of agriculture: do modern humans (*Homo sapiens urbanensis)* have greater food security because of agriculture and domestication – or might our species actually be less secure today because of modern, more technical approaches to agriculture?

Glossary

Accession A distinct, uniquely identifiable biological sample representing a variety, breeding line, or population maintained in storage for conservation and use.
Cryopreservation A technique of preservation of cells or tissue at the temperature of liquid nitrogen.
Genotype The genetic constitution of an individual organism.
Germplasm The genetic material that forms the physical basis of heredity and that is transmitted from one generation to the next by germ cells.
Phenotype The external appearance of an organism that results from the interaction of its genetic composition (genotype) with the environment.
Phytosanitary Relating to plant health and the control of pests and diseases.
Polyploid The presence of multiple sets of chromosomes beyond the usual two, in some cases rendering organisms sterile.
Regeneration Growing out of seeds of an accession to obtain a fresh sample with high viability and a sufficient quantity for conservation and use.
Somaclonal variation Changes observed in plants as a result of genotypic variation caused by growth in tissue culture.
Subculture The excision and transfer of a plant part from an aged culture medium to a fresh culture medium for renewal and strengthening.

Origins of *Ex Situ* Conservation

Plant genetic resources (PGR) provide the food and fabric of our livelihoods, determining the security or insecurity of 7 billion human lives. Evidently our ancestors showed a great interest in plants and a talent for nurturing and domesticating those that showed valuable attributes. The generations of farmers that followed them have developed and dispersed a vast diversity of domesticated crop varieties, which have adapted to local climates, conditions, and tastes. Scientists avoid answering questions such as "How many varieties of crop are there?" Suffice it to say that there are a few hundred crop species and a few million crop varieties.

Farming communities selected and conserved the plant diversity that they found useful, distributing it to the wider community and passing it down through the generations, as they still do. Such practices took on a more ambitious scope during the expansion of successful civilizations, such as the Romans in Europe, the Harappans in Asia, or Inca in Latin America, resulting in the wide dissemination of certain staple crops. An early protoscientific interest in crop diversity was expressed by the Ancient Egyptians, who organized collecting missions to acquire new plants (Plucknett *et al.*, 1987). Gatherings of plants for practical uses were organized into the first *ex situ* collections in botanical gardens associated with early medical institutions, monasteries, and royal palaces. These collections would have served to demonstrate the use of plants and to allow their study. The conservation of crop diversity remained solely in the hands of farmers and growers until the twentieth century.

By the end of the nineteenth century, scientists were taking a closer interest in agriculture. The term 'landrace' was coined for a locally adapted variety (Zeven, 1998). A few decades later, the pioneer collector and geneticist, Nicolai I. Vavilov opened up the study of crop genetic resources by describing the global patterns of crop diversity according to eight 'centers of origin' (Vavilov, 1949). Scientific breeding took off in the 1940s, and to support it large *ex situ* crop collections were brought together and formally managed in the USA, the Soviet Union, and Europe (Plucknett *et al.*, 1987). These collections provided breeders with an essential resource for crop improvement and vastly facilitated the international exchange of materials. The modern varieties that resulted from these efforts defied expectations for agricultural production and provided the basis for what is now known as the Green Revolution. Mexico, as a frequently cited example, previously imported half the wheat it consumed. In the two decades after the adoption of semidwarf wheat varieties, yields increased eightfold, bringing a new wealth to the country and paving the way for the economic development that followed.

The success of scientific breeding programs led to the intensification of agriculture and the spread of modern varieties.

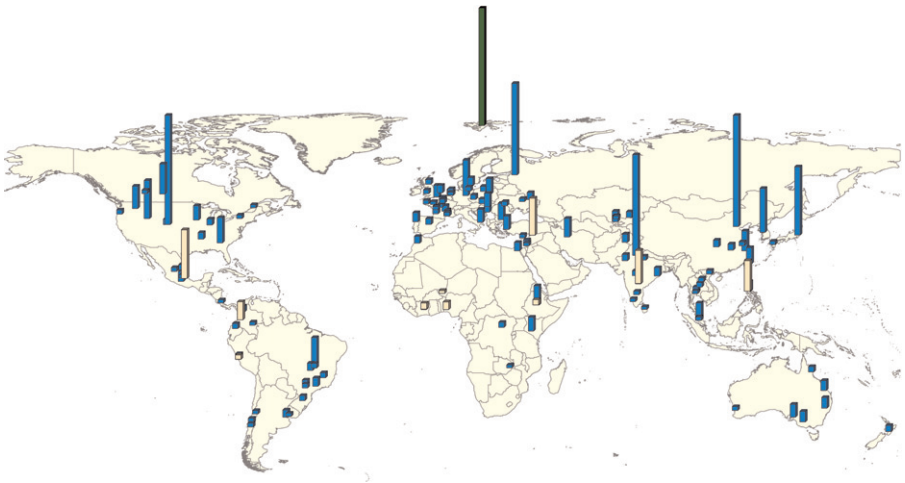

Figure 1 Geographic distribution of genebanks with holdings of more than 10 000 accessions (national and regional genebanks in blue, CGIAR centers in beige, and the Svalbard Global Seed Vault in green). Reproduced with permission from FAO, 2010. The Second Report on the State of the World's Plant Genetic Resources for Food and Agriculture. Rome, Italy: Food and Agriculture Organization of the United Nations.

As the adoption of modern varieties increased, growing concern for disappearing traditional landraces and the genetic diversity that they represented spurred further collection and conservation of crop genetic resources (Frankel and Bennett, 1970). The International Board for Plant Genetic Resources (IBPGR), now known as Bioversity International, was set up to coordinate this collecting effort from 1974. The major international breeding and research programs were also now organized in a public-funded consortium known as the Consultative Group on International Agricultural Research (CGIAR). The importance of ensuring crop diversity continues to be made publicly available was reaffirmed in 1994, when the collections associated with the CGIAR became formalized as international collections held for the public good under the auspices of the Food and Agriculture Organization (FAO) of the United Nations.

The expansion of *ex situ* collections, both in size and number, continued in the 1980s and 1990s. FAO reports that 7.4 million accessions are presently held in 1750 genebanks (**Figure 1**; FAO, 2010), apparently representing 70% of the genetic diversity of 200–300 crops (SBSTTA, 2010). These genebanks range from large public collections with global or regional coverage to national collections maintained by formal sector agricultural research institutions or universities to collections of local heirloom cultivars held by nongovernmental organizations. Private sector seed companies both large and small also maintain collections but these are not included in these figures as data on holdings are not generally made public. **Table 1** outlines the *ex situ* conservation of the 20 most represented crops in genebanks. In addition, some 2500 botanic gardens conserve 80 000 plant species, including many of economic importance (FAO, 2010). The Millennium Seed Bank (MSB) of the Royal Botanic Gardens, Kew, is the largest *ex situ* collection of wild plant diversity and conserves more than 10% of the world's flora. Most nations of the world now boast a new and powerful resource for future agricultural development in the form of genebanks.

How to Keep Plants in Storage Alive

Seeds of most major crop species are orthodox (e.g., sorghum, rice) and may be stored in dried form at low temperature for several decades and potentially up to several thousand years. Seeds of some species from some plant families or ecological origins, although it is hard to predict which, exhibit relatively short shelf life (Hay *et al.*, 2012; Nagel and Börner, 2009; Probert *et al.*, 2009; Walters *et al.*, 2005) and are intermediate in storage behavior (e.g., lettuce, barley). Some species (e.g., cacao, coffee) produce seed that are recalcitrant. They do not survive drying or storage at all. Finally, there are species that are propagated vegetatively through roots, tubers, and suckers. Species with recalcitrant seed and vegetatively propagated species and crops must be conserved using other methods, in field genebanks or in tissue culture.

The objectives of a genebank usually focus on maintaining the viability and genetic integrity of the stored samples at the best possible levels for the longest possible time. Genebank procedures have been researched and described extensively and will not be covered in detail here. The international community has also agreed standards for genebank procedures for seed crops to guide operations and help ensure quality (FAO/IPGRI, 1994). A revised version of these standards is now published and separate standards are available for non-orthodox seeds and clonally propagated plants (see FAO guidelines from the FAO website given in the Relevant Websites section). Bioversity International has published comprehensive technical guidelines and handbooks for genebanks (see Relevant Websites section for the website address). The Royal Botanic Gardens, Kew, provides online access to a Seed Information Database at see address in the Relevant Websites section and Smith *et al.* (2003) have compiled an invaluable resource, covering scientific research and practice in all areas of seed conservation from collection to use.

A specific understanding of the biology of the crop, together with an intimate awareness of the origin of the accessions in

Table 1 Twenty crops most numerically represented in *ex situ* conservation

Top 20 food crops held in ex situ *conservation*	*Total accessions worldwide*	*Coverage*	*Countries holding the largest collections, international and national genebanks*
Wheat	856 168	More than 200 collections exist. Landraces and modern cultivars are relatively well represented. Genetic stocks are more likely to be found in research institutes. Collecting of wild relatives is needed.	CIMMYT, USA, China, India, ICARDA
Rice	773 948	More than 175 collections with large collections in Asia. Landraces, modern cultivars and genetic stocks are well represented. Wild relatives are represented mainly in 2 collections.	IRRI, India, China, Japan, Republic of Korea, USA
Barley	466 531	More than 75 institutes conserve barley. A large part of the crop diversity is represented *ex situ*. Collections are made up predominantly of landraces, also breeding materials, modern cultivars, genetic stocks, and wild relatives.	Canada, USA, Brazil, ICARDA, Japan, Germany
Maize	327 932	Existing collections hold wide diversity but landraces from the Amazon, parts of Central America and Southeast Asia are inadequately conserved. Hybrids, certain inbred lines, and wild relatives also need better coverage. Some high-altitude varieties are very difficult to regenerate in the right conditions and perhaps better conserved *in situ*.	CIMMYT, Portugal, USA, China, Mexico, Russia
Beans	261 963	Several bean species are cultivated and represented in *ex situ* conservation. Some 70 wild species are included in genebank collections. Detailed gap analyses have been done by CIAT to identify priority species for collecting.	CIAT, USA, Brazil, Mexico, Germany, China
Sorghum	235 688	Some 30 institutes conserve sorghum. There are gaps in coverage of diversity from W Africa, Central America, Central Asia, and Sudan.	ICRISAT, USA, China, India, Ethiopia, Brazil
Soybean	229 944	Important collections exist in China, including traditional varieties that are no longer found in farmers' fields. One of the major crops that are not included in the International Treaty on Plant Genetic Resources for Food and Agriculture (ITPGRFA).	China, USA, Republic of Korea, World Vegetable Center, Brazil, Japan
Oats	130 653	Oats are conserved in a few very large collections and many smaller collections. Important collections of threatened wild species exist in the center of diversity in the Mediterranean.	Canada, USA, Russia, Germany, Kenya, Australia
Groundnut	128 435	Diversity from centers of origin is well represented in genebanks. More materials from other areas and wild relatives need to be collected. Some of the wild species are conserved in field genebanks. One of the major crops that are not included in the ITPGRFA.	ICRISAT, India, USA, Argentina, China
Cotton	104 780	Cotton is the best-represented fiber crop in *ex situ* conservation. Some 45 wild species are conserved among eight major collections but several areas of the genepool are underrepresented and under threat in the wild. One of the major crops that are not included in the ITPGRFA.	Uzbekistan, USA, India, China, Russia, France
Chickpea	98 313	Nearly 50 institutes conserve collections mainly of chickpea landraces. There are some wild species in *ex situ* conservation. Gaps exist in coverage from Central Asia and Ethiopia. More wild species need to be collected. Some are perennial and will need to be conserved in field genebanks.	ICRISAT, India, ICARDA, Australia, USA, Iran
Potato	98 285	Diversity is quite well represented, mostly in 30 key institutes. The widest diversity is held in collections in Latin America from where the potato originates. Collections include wild species but more diversity remains to be collected. *In situ* conservation is particularly important. The crop is conserved as seeds, tissue culture, or as plants in the field.	France, Russia, CIP, Germany, USA, Japan
Pea	94 001	There are 16 major collections comprising mainly cultivated forms, with some highly diverse wild relatives. Representation of wild species needs to be improved.	Australia, Russia, ICARDA, Germany, USA, Italy
Medicago	91 922	Medicago is a genus of temperate forages, which includes cultivated alfalfa and numerous wild species. It is one of the best-represented taxa in forage collections. The Rhizobia bacterial strains that are associated with legume crops and provide their nitrogen-fixing properties are also held in *ex situ* conservation. More collecting is needed, especially in rangelands that are rapidly disappearing.	Australia, Uzbekistan, ICARDA, USA, Morocco

(*Continued*)

Table 1 Continued

Top 20 food crops held in ex situ *conservation*	*Total accessions worldwide*	*Coverage*	*Countries holding the largest collections, international and national genebanks*
Tomato	83 720	Collections include modern cultivars, landraces, genetic stocks, and a small but very important number of accessions of wild species.	World Vegetable Center, USA, Philippines, Germany, Russia, Japan
Trifolium	74 158	Predominantly wild species are conserved with some cultivars of a few cultivated species. The Rhizobia bacterial strains that are associated with legume crops and provide their nitrogen-fixing properties are also held in *ex situ* conservation. More collecting is needed, especially in rangelands that are rapidly disappearing.	Australia, New Zealand, ICARDA, Great Britain, Spain, USA, ILRI
Rubber	73 656	Malaysia holds by far the largest collection with nearly 60 000 accessions. One of the major crops that are not included in the ITPGRFA.	Malaysia, Indonesia, Côte D'Ivoire, Liberia, Brazil, Vietnam
Capsicum peppers	73 518	More than 30 species of *Capsicum* are conserved, several of which have commercial value. One of the major crops that are not included in the ITPGRFA.	World Vegetable Center, USA, Mexico, India, Brazil, Japan
Prunus	69 497	Prunus includes cherry, plum, peach, and almond as well as other fruit and timber tree species. The seeds are difficult to conserve so generally whole trees are conserved in the field, including wild species, local varieties, and modern cultivars. One of the major crops that are not included in the ITPGRFA.	Russia, USA, Italy, Hungary, Turkey
Pearl Millet	65 447	ICRISAT's collection holds a third of global pearl millet accessions. The collection is made up mostly of landraces. Relatively few wild species, improved varieties, and breeding materials are held in collections. More collecting is needed.	ICRISAT, Brazil, India, France, Canada

Note: Vegetative propagated crops are conserved in relatively small collections and are underrepresented in this table.

the collection, contribute to determining the appropriate size and structure of a collection, the way the accessions are managed, regenerated, and made available, as well the acquisition of new germplasm. The methods used to sample and collect germplasm from farmers' fields or other sites have a profound impact on its subsequent long-term conservation and use (Rao *et al.*, 2006). The state and stage of development of the plant material is critical to its long-term storage. Guidelines and standards for collecting are provided by Guarino *et al.* (1995a), and also in updated form at the Crop Genebank Knowledge Base (see address in the Relevant Websites section).

Seed Genebanks

Approximately 90% of accessions in *ex situ* collections are held as seed (Rao *et al.*, 2006). Seed genebanks follow common procedures to process and conserve seeds as illustrated in **Figure 2**.

Drying

To introduce a seed accession into a collection, first the sample is cleaned and processed for storage. Moisture content is the most important factor that influences the longevity of orthodox seed in storage and should range between 3 and 7% (Rao *et al.*, 2006). The drying of the fresh seed sample before conservation is thus one of the most essential steps in the conservation process.

Seed Storage

In an active genebank, accessions are regularly accessed and used. Every transaction, whether it is removing a subset of seeds for a trial or planting seeds out to refresh the stock, has the potential to change the genetic composition of the original seed sample. For this reason, genebanks normally keep a sample of the original dried seed undisturbed in hermetically sealed containers in long-term storage conditions (at −18 °C). Another sample in medium-term storage (at 5 °C) is used as the active source of material for distribution, research, or planting. A description of this arrangement is described by Sackville Hamilton *et al.* (2003a).

Germination Testing and Regeneration

The predicted seed longevity in storage governs the frequency at which the samples are monitored. Monitoring involves removing a small subsample of seeds to test their germination. In an optimal situation, samples are monitored at regular intervals and regenerated to produce fresh seed when the viability or numbers of seeds in the sample drop below an acceptable level for storage or use. Sackville Hamilton and Chorlton (1997) have authored a decision guide to help determine the timing and effective procedure for regeneration. Standards currently advise that at least 85% of the seed sample should be viable for cultivated accessions and somewhat less for accessions of wild species (FAO/IPGRI, 1994). The process of regeneration demands individual procedures for each crop.

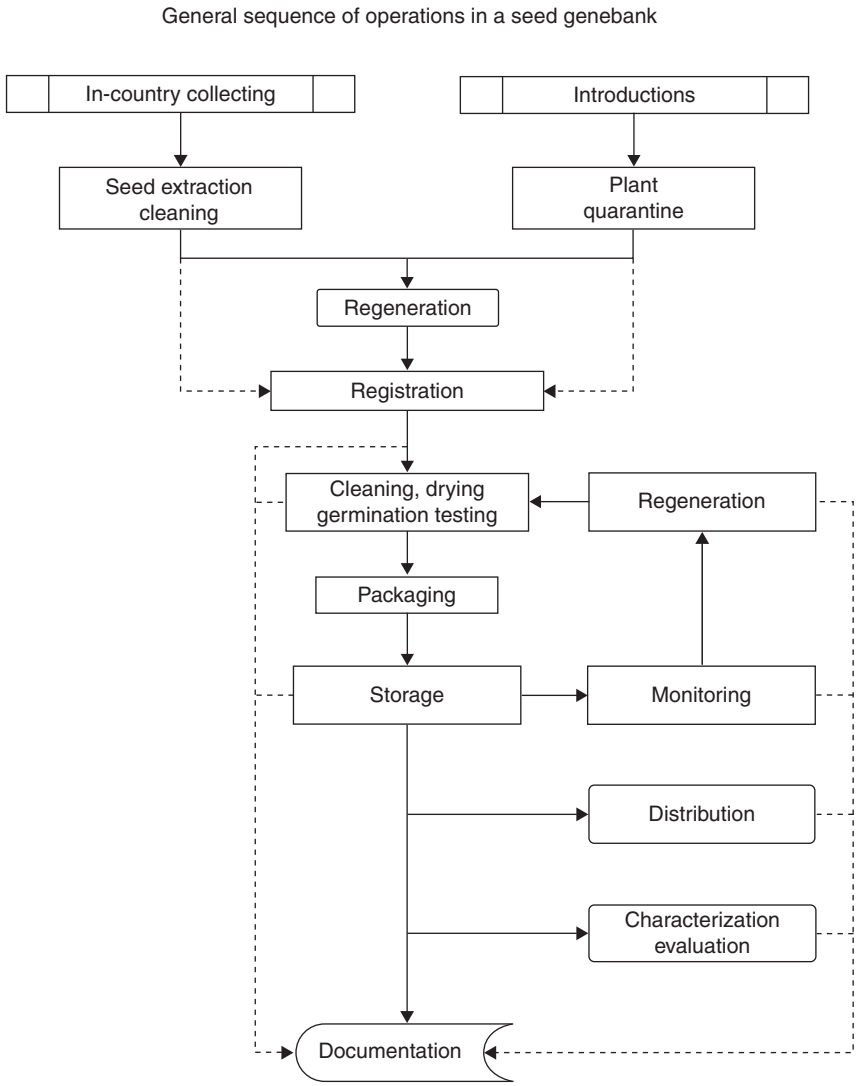

Figure 2 General sequence of operations in a seed genebank. Reproduced with permission from Rao, N.K., Hanson, J., Dulloo, M.E., *et al.*, 2006. Manual of seed handling in genebanks. Handbook for Genebanks No.8. Rome, Italy: Bioversity International, 147 pp.

These have been documented in guidelines (Dulloo *et al.*, 2008). Self-pollinating species are relatively straightforward to regenerate but for species that outcross, some form of controlled pollination is usually necessary to prevent one accession mixing with another. Regeneration is generally minimized as much as possible, especially for outcrossing species, as it heightens the risk of changes in genetic composition of an accession through unintentional selection, gene flow, and genetic drift (Chebotar *et al.*, 2003; Parzies *et al.*, 2000).

Difficult-to-Conserve Species

Many temperate and tropical fruit crops and most root and tuber crops are propagated vegetatively or produce seed that is recalcitrant to drying and cold storage. Collections of these species depend on the conservation of the entire plant in the field or of plantlets in tissue culture, and involve an entirely different procedure to the conservation of seeds (**Figure 3**).

Field collections take up large amounts of space, are expensive to maintain, and suffer regular and inevitable losses of accessions to pests, diseases, and adverse weather. On the positive side, accessions are readily observable and relatively easy to study and evaluate. As an alternative or more usually as a complement to field collections, shoot cultures may be maintained on a growth-retarding medium in test tubes in the laboratory. Tissue culture became viable as a conservation technique in the 1980s and has since been routinely adopted in international genebanks and in some national genebanks. Its use is most convenient for the short-term production of clean planting material but some institutes are successfully implementing protocols for tissue culture for medium-term conservation.

Operations in tissue culture genebanks revolve around maintaining the health of the accession sample and extending the duration of the interval between subcultures (Benson *et al.*, 2011; Reed *et al.*, 2004a). The sterility of media and equipment and the daily monitoring of cultures are of

Figure 3 Tissue culture of cassava at International Centre for Tropical Agriculture (CIAT) (photo credit Global Crop Diversity Trust).

critical importance, as is the timely subculturing of plantlets before they have outgrown the test tube or exhausted the medium. Reducing temperature and light intensity helps to slow the growth of cultures but few laboratories are able to extend the subculture period of the major part of their collections beyond 12 months. Certain genotypes and wild species require much more frequent subculturing. Conservation standards for recalcitrant seed and vegetatively propagated species are under preparation (see FAO draft guidelines from their website given in the Relevant Websites section).

Tissue cultures are continually growing and they do not need regeneration in the same way as seeds. However, the periodic rejuvenation of tissue cultures in the field has been considered a necessity to identify somaclonal variants, which can appear because of the stresses of tissue culture (Jain *et al.*, 1998; Withers, 1993). Experience with longer-term tissue culture or cryopreserved collections suggests that tissue culture does not produce significantly more somaclonal variation than field conditions (Reed *et al.*, 2004a; Keller *et al.*, 2008). However, the tissue cultures of some crops age with repeated subculture and become vulnerable to endophytic bacteria (Keller *et al.*, 2011), eventually requiring renewal.

Cryopreservation

The most secure method of long-term conservation for both seeds and tissue culture is cryopreservation whereby plant materials are stored in liquid nitrogen and chilled to a temperature of −196 °C. At this temperature, cellular and metabolic processes are slowed to a virtual standstill. Germplasm in liquid nitrogen is generally believed to be storable for an indefinite period without the loss of viability (Engelmann, 1997), although recent empirical studies on seeds have detected some deterioration in cryopreservation depending on the conditions in which they were previously stored (Walters *et al.*, 2004). For large collections of some crops, cryopreservation presents the only feasible conservation alternative to field conservation (e.g., coconut, coffee, garlic) (**Box 1**).

Germplasm Health

All genebanks are concerned with the health of accessions, particularly collections of whole plants or tissue cultures where contamination and infection occurs and spreads easily. The importance of avoiding the distribution of diseased materials, particularly across international boundaries, cannot be overemphasized. Crop-specific guidelines have been published on the safe movement of germplasm (see Bioversity International website given in the Relevant Websites section). Phytosanitary controls exist in most countries to reduce the risk of spreading specific crop pests and diseases. The use of diagnostic tools to detect pathogens has evolved rapidly with the introduction of molecular techniques, and accessions in active collections are usually submitted to health tests upon arrival into and dissemination from the collection. In cases of very high risk, such as the virus-prone banana, electron microscopy is used to detect any unknown virus particles or mycoplasma. Developing methods of cleaning diseased materials is also, by nature, an active area of research, which exploits various therapies involving temperature or chemical applications.

Characterizing and Documenting Accessions

Data are required in genebanks at multiple levels to manage samples, and to identify and classify accessions, and to help the user make informed decisions. Each sample is accessed into the collection with passport data to document its origins. Its accurate identification and classification is dependent on characterizing the principal morphological attributes of the living plant. Generic and crop-specific descriptors are available to help standardize the data gathered during characterization (see Bioversity International website given in the Relevant Websites section). The genebank user, however, is generally seeking information on the attributes relating to the use of the accession, such as its yield, pest and disease-resistance, and consumer qualities. These characteristics are not covered in standard descriptors but can be gathered through specific replicated and often multilocational evaluation trials.

Safety Duplication

An important responsibility for any genebank is to ensure that all unique accessions are held in an alternative location as a security measure in the event of a catastrophe or accidental loss. Civil war, natural disasters, fires, and diseases can claim unique collections of crop diversity in minutes. National and international genebanks in Afghanistan, Egypt, Iraq, and Syria have been recently looted or damaged during periods of unrest. In the past year alone, fire and floods destroyed major genebanks in the Philippines and Thailand.

Duplicated accessions may be treated as 'black box'; they remain effectively unopened and untouched unless requested by the donor. The Svalbard Global Seed Vault provides a new level of safety duplication for seed genebanks. This facility is described in the photograph given in **Figure 4**.

Box 1 Cryobanking

Research on the cryopreservation of plant genetic resources over the past 20 years has established protocols for approximately 200 crop species. Protocols are not only highly crop specific and sometimes genotype specific but their successful application is heavily influenced by the culture, skills, and experience of the practicing technicians and laboratory (Reed *et al*., 2004b). Several international and national genebanks are now refining protocols specifically for cryobanking the crop collections under their management. More than one protocol may be required to cryopreserve all the genotypes in a single crop species (Panis, 2009).

Currently used cryopreservation techniques include the dormant bud method, controlled freezing, vitrification, encapsulation, and droplet methods (Keller *et al*., 2011). Research and refinement of protocols focus on improving the rates of postthaw regeneration of cryopreserved plant material by examining variables such as explant size, dehydration conditions, cryoprotection, and speed of temperature reduction (Keller *et al*., 2011). Research is also aimed at developing tools to help genebank managers determine which protocols are best suited to which genotypes.

A few genebanks are cryopreserving accessions as a routine operation or maintaining sizeable cryobanks. The largest cryobank collections of vegetatively propagated crops comprise the collection of apple and vegetatively propagated crops (3750 accessions) at the National Center for Genetic Resources Preservation of the US Department of Agriculture; cassava, the potato, garlic, and mint collections (1300 accessions) at the Leibniz Institute of Plant Genetics and Crop Plant Research in Germany; the global banana collection (880 accessions) managed by Bioversity International; and the cassava core collection (640 accessions) at the International Center for Tropical Agriculture (CIAT), Colombia. A significant number of accessions have been cryopreserved of collections, including European Elm managed in a collaboration between French and German research institutes; potato at the International Center for Potato (CIP) in Peru; hops and potato at the Crop Research Institute in the Czech Republic; and mulberry and garlic in national genebanks in Japan and South Korea, respectively.

Cryopreservation is presented as a cost-effective long-term alternative to other forms of conservation (Dulloo *et al*., 2009; Koo *et al*., 2004; Li and Pritchard, 2009). Cryopreservation is also an effective method to eliminate viruses (Keller *et al*., 2011; Wang *et al*., 2008). However, cryobanking in the plant world has proven slow to take off. There are substantial startup and recurring costs to train and sustain the highly skilled staff, develop and refine protocols, ensure continuous liquid nitrogen supply, and prepare source materials in sufficient quantities. Furthermore, the rate at which cryopreservation currently takes place can severely limit the number of accessions that can be cryopreserved. The target tissue is pared down to a minimum size in order to limit the effects of the damage and subsequent oxidation of the tissue. The technique demands surgical skill. Several hundred samples of a single accession must be cryopreserved to guarantee successful regeneration (Dussert *et al*., 2003). Presently, a fully skilled technician may be able to cryopreserve between 50 and 100 accessions per year. Cryobanks of vegetatively propagated crops, therefore, are not accessible for general routine use and cannot entirely replace active tissue culture or field collections. The chief importance of cryobanking is to provide a secure form of long-term conservation. Closer collaboration between practicing institutes is advocated by several practitioners to make better use of cryopreservation (Keller *et al*., 2011; Lerman *et al*., 2009). In the animal world, a coalition of institutes is cryopreserving threatened amphibian species in the *Amphibian Ark* (Lerman *et al*., 2009).

Cryopreservation of dormant buds and seeds is considerably less costly than that of excised tissues. USDA maintains a collection of more than 35 000 cryopreserved seed samples. For seed crops, cryobanking presents not only a unique opportunity for improving the long-term security of the collection but also a means to reduce the need for costly germination testing and regeneration. Li and Pritchard (2009) highlight the fact that approximately 26% of species with apparently orthodox seed do not store well at −20 °C under conventional seed genebank conditions (Probert *et al*., 2009). Cryopreservation may be a more effective form of long-term conservation for these species.

Maintaining Standards

Although a rich resource of crop-specific and generic guidelines and standards exist, individual genebanks will invariably need to modify their procedures according to the precise complement of crops being conserved, the use and objectives of the genebank, available expertise, and the conditions under which they are functioning. Compliance with standards depends on adequate resources. In all cases, the development of an operation manual is essential for every *ex situ* collection and is the basis for achieving any kind of quality standard for the genebank. Sharing standards is also important in moving toward closer collaboration and sharing responsibilities between genebanks (Sackville Hamilton *et al*., 2003b).

Brief Glimpses into Genebanks

The Svalbard Global Seed Vault (**Figure 4**) is not a conventional genebank. It is a security bank for duplicates of seed samples from genebanks worldwide. Built into the permafrost of an ice-covered mountain within the Norwegian Arctic Circle, the vault will keep seeds frozen even with a loss of power.

The door of the vault opens only three times a year, during which time deposits are made by genebanks who wish to safety duplicate their accessions in 'black box.' This means that only the depositor is able to request access to the seeds that they send. Even the Svalbard genebank manager asks for permission from the depositor to access the deposits should a bag or crate require repairs. This arrangement is sealed with a Standard Depositors' Agreement.

The International Coconut Genebank (**Figure 5**) managed by Center National de Recherche Agronomique in Côte D'Ivoire conserves 99 accessions of coconut, each comprising at least 100 palms and covering more than 1000 ha. Collecting pollen, pollinating flowers, and harvesting the seednuts from the 20 m-tall trees is a major part of the annual workplan. The germplasm maintained here is provided to coconut breeders around the world. It is a valuable resource, yet it is at risk. Not far away in neighboring Ghana, a coconut

Figure 6 Maize accessions at CIMMYT (photo credit Global Crop Diversity Trust).

disease called Lethal Yellowing is destroying plantations. It is essential that this unique collection be adequately safety duplicated.

The International Maize and Wheat Improvement Center (CIMMYT) in Mexico (Figure 6) specializes in the conservation of wheat and maize. The two collections together comprise more than 170 000 accessions originating from more than 100 countries. Both collections date back several decades and include the original materials used in the Green Revolution. The maize collection includes a number of highly endangered wild maize, or teosinte, subspecies.

Wild bananas produce seeds, but most cultivated forms have lost them. The most common way to conserve bananas is as whole plants in the field. It is possible to distribute banana germplasm from field genebanks as plant suckers, but the germplasm is quite likely to harbor pests and disease no matter what cleaning measures are in place. Bioversity International conserves and provides a wide range of banana diversity as clean tissue cultures from its collection held in the Katholieke Universiteit of Leuven, Belgium.

In the Solomon Islands, an archipelago of small, isolated islands, the available infrastructure does not favor conserving such a vital crop as banana in a centralized genebank. A nonprofit organization, The Kastom Garden Association works with local farmers to conserve banana in a network of community genebanks. Dorothy Tamasia (Figure 7) is one of these farmers. She conserves a small but diverse collection in a plot near her village on the island of Makira.

Complementarity Between *In Situ* and *Ex Situ* Conservation

Typically *ex situ* conservation is considered to be static in evolutionary terms in comparison with *in situ* conservation (Bretting and Duvick, 1997). Indeed, it is an important objective of a genebank to maintain genetic stability so that users

Figure 7 Dorothy Tamasia, Solomon Islands (J. Daniells).

may be assured of the trueness-to-type of the material they are requesting. Both *ex situ* and *in situ* conservation share the same objective to enhance or promote the value of individual varieties or accessions in order to assure their conservation. The target audiences are different, however. Genebanks are generally targeting researchers and breeders at a national or international level. *In situ* conservation efforts are generally managed at a local or experimental scale, targeting farmers, traders, processors, or local communities. *In situ* conservation cannot be easily designed to support wide scale availability of germplasm or to provide long-term security (Engels and Visser, 2003a; Fowler and Hodgkin, 2004; Jarvis *et al.*, 2000, 2004; Visser and Engels, 2003a).

The *ex situ* conservation of some crops, however, remains technically challenging and expensive. For most vegetatively propagated species and crop wild relatives, the conservation of the entire genepool depends heavily on conservation by farmers and managers of natural landscapes or protected areas (Fowler and Hodgkin, 2004). *In situ* conservation initiatives are gaining momentum in numerous countries, although up until now they are focused on inventorying and prioritizing *in situ* sites (FAO, 2010). The coverage of crop diversity and the potential effectiveness of *in situ* conservation in safeguarding diversity over the long term under present-day climate and conditions remain largely unknowable at present.

Genebank Use and Impact

Role of Genebanks

Genebanks provide a broad range of diversity for use, including modern cultivars, obsolete cultivars, breeding lines, traditional varieties, and wild relatives. Conventionally, they feed directly into breeding programs, providing the raw materials from which new modern varieties are developed. Breeders may keep their own working collections of the materials that they are currently using, but only genebanks have the capacity to store a wide range of diversity in long-term conservation. Genebanks also contribute to research that leads to the development of new varieties. In a survey of four major (non-PGR specialist) crop science journals, 191 out of 859 (22%) articles published in a single year involved the access and use of more than 36 000 samples of 112 species. Eighty percent of these articles sourced their materials from genebanks in 27 countries and seven CGIAR centers (Dudnik *et al.*, 2001).

There are uses for genebank material apart from breeding and research. Genebanks may play a role in disseminating materials directly to farmers. For clonal crops, genebanks provide disease-cleaned tissue cultures, which can contribute dramatically to increasing yields. A potato cultivar, Achirana INTA from Argentina was distributed by International Center for Potato (CIP) as a pathogen-free variety to China where it was released as CIP-24 (Thiele *et al.*, 2008). Surveyed users of the global banana collection, managed by Bioversity International, state the most important reason for using the genebank is the reliable, virus-free status of the germplasm (Garming *et al.*, 2010).

Genebanks also provide backup sources of seed in the event of a disaster. Seeds were provided from genebanks to redevelop agriculture after civil war in Angola and Rwanda, and after widespread damage caused by adverse farming policies in Cambodia. Genebanks were called upon to restore planting material and seed after Hurricane Mitch in Central America.

Promoting Use

The active use of a genebank depends on the availability of the material conserved within it. Fowler and Hodgkin (2004) distinguish the concepts of 'access,' a measure of the legal attainability of germplasm, from 'availability,' which relates to whether the material can be identified and obtained in a usable form. The availability of an accession is influenced by multiple factors, which extend back to the moment when it is first collected. It touches upon the nature and quality of the material, the quantity and form in which it can be provided, and most particularly the information associated with it to identify it and indicate its potential value and application. Much of the work of an active and well-resourced genebank is dedicated to making material available through maintaining viability, health-testing and disease-cleaning, structuring the

collection, and most directly through evaluating accessions and improving accession-level information to promote use.

Several important mechanisms have been developed in recent years to promote the use of diversity and genebank collections.

- Core collections include a minimum number of well-documented and identified accessions as a means to showcase or represent genetic diversity (van Hintum *et al.*, 2000) and to provide an entry point into the wider collection. If an initial search of the core collection produces something of interest, the user may search the particular branch of diversity that is of interest in more depth. Some large collections reduce their core sets even further into minicores (1% of the entire collection) or trait-specific subsets (Upadhyaya *et al.*, 2008).
- Focused identification of germplasm narrows the search for certain adaptive traits by identifying accessions originating from specific environmental or climatic conditions that are associated with those traits (Street *et al.*, 2008). The approach has helped identify barley and wheat accessions with resistance to certain fungal pathogens and Russian wheat aphid (El Bouhssini *et al.*, 2011; Endresen *et al.*, 2011).
- Evaluation, base broadening, and prebreeding are all activities that create attractive products for further research and breeding. The level of involvement of genebanks in these activities is controversial, especially for major crops such as rice, which have well-developed programs for crop improvement. For many less well-resourced crops, the genebank may be the best place, if not the only, facility for carrying out these activities. In all cases, strong feedback loops between genebanks, breeders, and users are essential.
- Significant investment has been made in developing or revising databases. The quality of data is also receiving increasing attention. van Hintum *et al.* 2011 have devised a passport data completeness index, which has been tested on data from European collections, as an aid to help raise data quality standards.
  - EURISCO (see Relevant Websites section) provides a catalog of more than one million accessions representing approximately half the number of accessions held in 318 genebanks in 42 countries in Europe.
  - Germplasm Resources Information Network (GRIN; see address in Relevant Websites) provides access to more than 500 000 accessions held in National Plant Germplasm System of the US Department of Agriculture. A comprehensive revision of this software, GRIN-Global, has recently been made freely available for general use by genebanks.
  - International Crop Information System (ICIS; see address in Relevant Websites section) provides pedigree information for wheat, rice, and maize collections.
  - GeneSys (see Relevant Websites section for address) brings together GRIN, EURISCO, and CGIAR center accession data, representing some 2.4 million accessions in one web portal.

Good quality data can strongly influence use. As a result of enabling search engines, such as Google, to index the data in GRIN, requests have increased by more than 80% in a period of 4 years. There is a correlation between web page hits and number of requests for germplasm from the genebanks (Bretting, 2012, personal communication).

International Distribution and Politics

Several economists have illustrated the importance of access to materials from numerous countries for the improvement of crops (Johnson *et al.*, 2003). Most genebanks provide germplasm to local users but few disseminate germplasm internationally (FAO, 2010). The CGIAR centers and a few major genebanks – national genebanks in Australia, Brazil, Canada, China, Germany, Netherlands, Russia, USA, as well as the Nordic Genebank, the Tropical Agricultural Research and Higher Education Center (CATIE), and the World Vegetable Center – are the source of the vast majority of international distributions. In the 12-year period up to 2010, the genebanks of the CGIAR centers plus the World Vegetable Center distributed more than 1 million samples of accessions, of which 77% were landraces and wild species (FAO, 2010).

The CGIAR breeding programs may disseminate more than twice the number of samples as the genebanks. In a 6-year period, CIMMYT alone distributed 1.2 million samples to over 100 countries through its international nursery system (Fowler *et al.*, 2001). However, genebanks disseminate a broad range of landraces and crop wild relatives, fulfilling a unique role in support of breeding and research (**Table 2**). Their role is not comparable to that of breeding programs, which at any one time disseminate large quantities of just a few improved

Table 2 Percentage of accessions of different types of crop resources distributed by the International Agriculture Research Centers to different users from 1996 to 2006

Type	*Within/between IARCS*	*NARS developing countries*	*NARS developed countries*	*Private sector*	*Others*	*Total number of accessions*	*Percentage of the total*
Landraces	57.9	48.5	45.0	51.7	65.7	194 546	51
Wild species	29.2	19.0	40.5	7.1	19.1	104 982	27
Breeding lines	8.5	23.1	5.4	36.0	6.5	56 804	15
Advanced cultivars	3.5	8.0	9.1	5.1	8.6	24 172	6
Others	0.9	1.4	0.1	0.1	0.1	3 767	1

varieties from breeding programs to national agriculture programs and farmers.

Germplasm distributions have been influenced by a changing political climate (Halewood *et al.*, 2012). International distributions were adversely affected by the adoption of the Convention on Biological Diversity (CBD) in 1992, which established national sovereignty over PGR and determined that if one country wanted to request resources from another, a process of attaining prior consent and agreement would need to take place in each case (Engels and Visser, 2003a; Tansey, 2008; Visser *et al.*, 2000). The International Treaty on Plant Genetic Resources for Food and Agriculture (ITPGRFA) came into force in 2004 to ensure that the major staple crops would remain easily available through a multilateral system (MLS) of access and benefit sharing (FAO, 2001). The MLS is embodied in a Standard Material Transfer Agreement (SMTA), which lays down standard terms and conditions for general use to ensure access to germplasm and sharing of any benefits derived from its use. The mechanisms for access and benefit sharing are still very much on trial. Although many countries are establishing national laws and mechanisms for accommodating the CBD, the ITPGRFA and now the Nagoya Protocol on Access and Benefit Sharing, which was adopted under the CBD in 2010, the full effects of these policy changes on international exchange of germplasm are yet to be seen. However, the movement of germplasm between more than 50 countries under SMTA, as part of a project funded by the Global Crop Diversity Trust to support national genebanks, provides tentative evidence of resurgence in international germplasm exchange.

Economic Impact

Numerous studies have assessed the impact of PGR in crop improvement and found high rates of return on investment particularly for major staple crops, wheat, rice, maize, and potatoes (Evenson, 2001; Evenson and Gollin, 2003; Renkow and Byerlee, 2010). The improvement programs of CGIAR centers for 10 crops made an average 25–33% annual contribution to crop yield increases across all geographical regions between 1965 and 1998 (Renkow and Byerlee, 2010). These contributions are of continuing or increasing importance, and in economic terms are worth billions of dollars (Evenson and Gollin, 2003).

According to Smale and Hanson (2010), only two studies have evaluated the specific contributions of genebanks to these impacts. There are multiple factors contributing to the lack of data on the value and impact of genebanks and their roles. Tracing the pedigree of improved varieties and the contributions and sources of ancestral materials is fraught with difficulty. Fowler and Hodgkin (2004) cite the Sonalika wheat cultivar, widely planted in the 1960s, with a pedigree which when printed out extends over 6 m. Few pedigrees are that well-documented. Breeders' logbooks and records of ancestral materials are of varying comprehensiveness and may include prebred materials, the origins of which are undocumented. Also many different factors, other than PGR, contribute to improved yields and economic benefits. The magical contribution of a winning trait from a specific variety is a relatively rare occurrence. The value of any one variety or gene is hard to disentangle and unlikely to be great (Smale and Hanson, 2010). Consequently economists have dwelled on the easier task of calculating the cost of maintaining crop diversity in genebanks and the marginal cost of adding accessions to collections, arguing that if the costs are low the benefits will always be higher (Smale and Hanson, 2010).

Table 3 Numbers of accessions screened at the IRRI genebank for resistance to specific pest and disease

Pest/disease	*No. of accessions screened in genebank*	*Resistance discovered (%)*
Brown planthopper biotype 1	44 335	15.4
Brown planthopper biotype 2	10 053	1.9
Brown planthopper biotype 3	13 021	1.8
Green leafhopper	50 137	2.8
Rice whorl maggot	22 949	3.0
White-backed planthopper	52 042	1.7
Zigzag leafhopper	2 756	10.1
Rice leaffolder	8 115	0.6
Yellow stem borer	15 656	3.8
Striped stem borer	6 881	<0.02
Blast	36 634	26.2
Sheath blight	23 088	9.3
Bacterial blight	49 752	11.1
Rice rugged stunt virus	13 759	2.4
Rice tungro disease	15 795	3.5

Genebanks are particularly useful, and their impact is likely to be great, when new problems occur and the necessary traits are not present in adapted germplasm in breeders' working collections. At times like these, breeders turn to the genebank to search for new genetic sources of traits. More than 11 000 accessions of landraces and primitive wheats have been screened in ICARDA genebank for resistance to the recent outbreaks of Ug99 strain of stem rust in wheat. Useful genes can be extremely rare, necessitating exhaustive searches to find them. **Table 3** provides numbers of rice accessions screened from the International Rice Research Institute (IRRI) genebank to locate resistance to major pests and diseases.

Theoretical models provide support for the argument that it is economically efficient to keep landraces unused in genebanks because of the potential pay-offs of finding specific traits in certain conditions over the long term (Gollin *et al.*, 2000).

Genebanks of the Twenty-First Century

Genebanks as Museums

Genebanks are sometimes ineffective at addressing the needs of breeders and farmers and function more like museums or, worse, morgues (Weidong *et al.*, 2000; Marshall, 1989). All genebanks have difficulty sustaining the necessary levels of expertise and trained staff to take care of or use the collections. In a project, coordinated by the Global Crop Diversity Trust, to

regenerate and safety duplicate threatened accessions held in national genebanks, 85 000 accessions were identified by 77 countries as requiring urgent regeneration. Slightly more than half of the institutes involved found that more than 10% of the accessions that they intended to regenerate were no longer viable and in half of these cases the loss in viability concerned 25% or more of the collection. A larger number were unable to produce sufficient quantities of seed for safety duplication. More than 65 000 accessions were regenerated but less than half of these have been safety duplicated and made available.

Where genebanks are resourced adequately, various factors contribute to lack of use. The appropriate management and ultimate availability of a crop collection is underpinned by a sound knowledge of the taxonomy of the crop and of how genetic diversity is distributed within the genepool (Jaradat *et al.*, 2004; Parzies *et al.*, 2000; van Treuren and van Hintum, 2001; van Treuren *et al.*, 2005). However, even for a major crop such as wheat, there are 14 taxonomic classification systems in use around the world and no undisputable way to identify botanical varieties (Pinheiro de Carvalho *et al.*, 2012). Issues of taxonomic identification of accessions are exacerbated by the inadequacy of passport data, mislabeling, changes in naming conventions, and changes in the genetic integrity of the sample during the course of genebank operations. Although the taxonomy of numerous crops remains a sticking point, stricter genebank procedure and standards have addressed other issues apparently with some success. A study of accessions in the lettuce collection held at the Center for Genetic Resources (CGN) showed that cultivars dating from before 1900 had more than 40% probability of being nonauthentic to their labeled identity, those released between 1960 and 1990 had a 10% rate of nonauthenticity, whereas those released in the past 20 years are all labeled correctly (van de Wouw *et al.*, 2011).

Large parts of any collection, no matter how well managed, will remain unused until its value is appreciated either through study or the rise of new pests, disease, or other needs. At any one time, only a small proportion of the available germplasm of a crop will have value (Sackville Hamilton *et al.*, 2003b). Robinson notes that the maize cob that contributed to the development of quality protein maize languished in a genebank for 30 years before its specific attributes were called upon.

There are also strong reasons for supposing that the use of genebanks will change dramatically in the future. Gollin *et al.* (2000) demonstrated that cost and time lags incurred when searching for pest and disease traits in unimproved wheat germplasm deter breeders from using unknown materials in genebanks. They predict that landraces and wild relatives will remain unused until molecular data reduce search time and costs. In a similar vein, McCouch *et al.* (2012) report, "Only a small fraction of the naturally occurring genetic diversity available in the world's germplasm repositories has been explored to date, but this is expected to change with the advent of affordable, high-throughput genotyping and sequencing technology."

This is already becoming a reality. Under the RiceSNP Consortium (see Relevant Websites section), several thousand accessions of rice from the IRRI genebank are being genotyped using high-density single nucleotide polymorphism (SNP) arrays, and 10 000 accessions are the subject of multiplex resequencing strategies (McCouch *et al.*, 2012). A significant part of the maize and wheat collections at CIMMYT are also being genotyped under a Mexican Government–funded project called Seeds of Discovery. The results will help determine the genetic diversity within and between accessions and provide the levels of detail needed to identify duplicates with confidence. Furthermore, linking genotype to detailed information on the phenotype of a critical number of accessions will enable any number of accessions to be screened for sought-after phenotypic characteristics or traits by using just their genotype data – a possibility that will make screening genebanks much quicker and more effective.

Such genotyping efforts are possible for all crops, although cross-pollinating species and polyploid crops pose challenges. However, the demands of managing and transcribing the vast quantities of data produced are on a scale of magnitude far beyond what any genebank has experienced to date. McCouch *et al.* (2012) continue, "While the power and cost of the new technologies have reached a level where we can begin to contemplate routine whole-genome genotyping or sequencing of entire collections, there is an urgent need to develop strategies and protocols for managing both sequenced germplasm and sequencing information in a rational and productive way."

Sustaining and Securing the CGIAR Collections

Long-term sustainable funding in the early years of the establishment of the CGIAR was critical to its contribution to the Green Revolution (Byerlee and Dubin, 2010). Since then, areas of research have vastly broadened within the CGIAR, whereas the focus of funding has become more restricted. In the 1990s, genebanks were experiencing diminishing support and funding (Clark *et al.*, 1997). The difficulties of keeping up with operating standards and backlogs of regeneration were becoming evident (FAO, 1998).

By the end of the last century, the CGIAR center genebanks were in crisis and emergency funding was sought by the CGIAR System-wide Genetic Resources Program to renew equipment, upgrade cold rooms, and clear the backlogs in regeneration, health-testing, and other routine operations, which had built up over years of inadequate funding. In response to the evident difficulty of attracting sustainable funding for routine genebank operations, the CGIAR together with the FAO established an endowment fund with the aim of financing the routine operations of priority crop collections from the annual income of the invested fund. The fund and disbursements are managed by an independent organization called the Global Crop Diversity Trust, which was established in 2004. The principles and criteria behind the use of the fund are described in a Fund Disbursement Strategy (see Relevant Websites section). Currently, grants are provided to 20 major crop collections to help support their routine management in perpetuity.

The hugely varying approaches to conservation operations is illustrated in a survey of expenditures on PGRFA conservation conducted by Virchow (1999) in 39 countries, which indicate that per accession costs range from US$1 to US$1293. If a genebank undertakes only the minimum activity required to keep seeds in a cold room or freezer, the costs of operation

may be kept as low as US$1 per accession. However, the collection will not remain viable for more than a few years. The operation costs of a number of international seed genebanks have been studied in some detail (Hawtin *et al.*, 2011; Koo *et al.*, 2004, Pardey *et al.*, 2001). The reproductive biology of the crop is the major determinant of the scale of the costs, varying widely between outcrossing and self-pollinated species and between seed and vegetatively propagated crops (Horna *et al.*, 2010). Health-testing, disease-cleaning, information management and characterization are also highly variable and costly. The most recent costing establishes per accession operation costs (not including capital costs) at US$3/accession for wheat compared with US$33/accession for tropical forages with an overall average of US$12/accession for seed accessions (Hawtin *et al.*, 2011). Clonal crops are substantially more expensive to conserve and distribute because of the labor-intensive nature of field and *in vitro* conservation and the average per accession cost is at least 10 times higher than that for seed crops.

The scale of the cost of conserving 7.4 million accessions worldwide to minimum acceptable standards raises the question of what actually needs to be conserved as a global priority. Fewer than 2.25 million accessions are actually believed to be distinct accessions (FAO, 2010). Part of the duplication of conservation efforts occurs because of the need for breeding and research institutes in different countries to have ready access to popular varieties (Hodgkin *et al.*, 1991; van Treuren *et al.*, 2010). However, unplanned and unnecessary duplications account for a significant proportion of recent increases in accession numbers.

This growing historical load borne by present-day genebanks and the need to rationalize collections has been a regular discussion point over the past decade (Engels and Visser, 2003b). Rationalization becomes all the more important when considering that the coverage of numerous crops needs to be improved (FAO, 2010), especially of crop wild relatives, which contain considerable amounts of untapped genetic diversity.

Some efforts at rationalizing collections have been made. CGN in the Netherlands is one of the few institutes that have expressed clear priorities: 80% of its core budget is dedicated to eight out of 20 crop collections based on user demand, representativeness, and availability of the germplasm elsewhere (Visser and Engels, 2003b). A European integrated genebank system (AEGIS) with minimum duplication is also being established (ECPGR, 2009). Other regions have also set up centralized facilities, which allow national programs to relinquish certain conservation roles. The Nordic Genebank represents Scandinavian countries, the Southern African Development Community Plant Genetic Resources Center conserves materials on behalf of South African countries, and the Center for Pacific Crops and Trees (CePaCT) conserves vegetatively propagated crops for the Pacific community.

Processes of rationalizing accessions are not straightforward and are potentially more costly than the savings made, especially for seed collections. In many cases, molecular markers are not powerful enough to be used for distinguishing accessions and eliminating duplicates (McCouch *et al.*, 2012), although they have been successfully used for some clonal crops (Motilal *et al.*, 2011). Rationalizing operations or limiting the availability of less-requested accessions may be more useful ways of cutting costs (Sackville Hamilton *et al.*, 2003b). The genotyping of a wider range of crops will present a tremendous opportunity to develop a more rationalized global system of genebanks.

A Final Word on the Future

Many genebank accessions are no longer available in the farmers' fields from where they were collected (Guarino, 1995b; Dulloo *et al.*, 2010; van de Wouw *et al.*, 2010). According to country reports to the FAO, genetic erosion in cereals appears to be the most severe (FAO, 2010). Pinheiro de Carvalho *et al.*, (2012) reviewed a number of studies that show massive loss of cereal landraces in European countries. According to bioclimatic modeling, genetic erosion from populations of wild relatives is projected to increase, causing the potential extinction of 16–22% of species such as peanut, potato, and cowpea (Jarvis *et al.*, 2008). Major shifts in crop climates are also predicted to occur, potentially causing major losses of crop diversity from existing cooler climates and the urgent need for crop diversity adapted to heat and drought (Burke *et al.*, 2009).

Conflicting results have been published on the trend in levels of genetic diversity within modern varieties, but recent findings suggest that, overall, the genetic base has broadened (van de Wouw *et al.*, 2010). The number of landraces in the pedigrees of Spring bread wheat varieties in developing countries increased from 24 in 1966 to 60 in 1997 (Smale *et al.*, 2002), and more than 2000 new varieties of wheat have been released in the developing world at an increasing rate over time since the 1960s (Dixon *et al.*, 2006). Genetic erosion is occurring in traditional varieties *in situ*, but the potentially dangerous trend toward diminishing genetic diversity in improved varieties, which started in the 1960s and 1970s, appears to have been reversed thanks to the establishment and use of genebanks, especially those of the CGIAR centers (van de Wouw *et al.*, 2010).

The value and use of particular crops or varieties change with time, markets, needs, and capacity of the users to exploit them (Fowler and Hodgkin, 2004). We have no way of accurately predicting what the future will demand and what crop diversity will be needed. *Ex situ* collections remain the best and most cost-efficient way to study, store, document, share, pass on, and make available the widest possible crop diversity to the widest possible audience of users, researchers, and breeders.

Genomics of Food Animals

JB Dodgson, Michigan State University, East Lansing, MI, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Contig It is a continuous region of the genome covered by overlapping sequence reads (a sequence contig) or BAC clone inserts (a BAC contig).

Expression quantitative trait locus (eQTL) A polymorphic allele that differentially affects the level of expression of a gene.

Linkage disequilibrium (LD) A nonrandom association of nearby alleles in a population; arises from preexisting allele configurations that are not yet randomized by recombination.

Library A collection of recombinant deoxyribonucleic acid (DNA) clones (e.g., a BAC library) or DNA fragments used in mapping and/or sequencing.

N50 The size of the smallest contig or scaffold such that 50% of the genome is covered by it and all larger contigs or scaffolds.

Orthologous genes (orthologs) A pair of genes from two species are orthologous if they derive from a single gene present in their last common ancestor; usually this means that they are the most homologous of all possible interspecies pairs (contrast to paralogous).

Paralogous genes (paralogs) A pair of genes from two species are paralogous if they evolved from two different genes both of which existed in the last common ancestor genome (contrast to orthologous).

Shotgun sequencing The process of accumulating manyfold coverage of random sequence reads from a target DNA, followed by computational reassembly of its complete sequence based on read overlaps.

Single nucleotide polymorphism (SNP) Single base changes for which both alleles segregate within a given population.

Sequence-tagged site (STS) Any unique sequence within the genome (usually small). These are often used to generate polymerase chain reaction fragments, hybridization probes, or to identify SNPs within the STS for use in linkage mapping.

Introduction

Genomics is a term first popularized by the journal of the same name, where it was described as being "born from a marriage of molecular and cell biology with classical genetics" and "fostered by computational science" by McKusick and Ruddle (1987), who also laid the foundation of genomics in the two complementary functions of mapping and sequencing of genomes. Little did they know at the time that genomics would be the prototype for a variety of related subdisciplines also given the suffix 'omics' to connote that one is addressing the complete genome and/or all of its components, rather than one gene or a small gene family.

Similar to all aspects of genetics, genomics explores the connection between genotype and phenotype, and the genomics of food animals primarily addresses economic traits related to agricultural productivity. Most of these are inherently polygenic traits influenced by alleles (polymorphisms) at numerous quantitative trait loci (QTL). Although a major focus of food animal genomics is to use genomic data to improve breeding, genomics is not simply a tool or a technology. It is a fundamental discipline that is essential to understand almost all aspects of animal biology. At the same time, progress in genomics is very much technology dependent, and few other aspects of biology have seen their tools evolve so rapidly. Most of these new techniques were first applied to either human biology or 'model' species (e.g., *Drosophila melanogaster* and *Caenorhabditis elegans*). As a result, food animal genomics often involves applying similar approaches to those already pioneered in medical/human genomics, and, despite the different practical uses to which they are put (meat, milk, eggs, and wool), genomic technologies used for almost all food animal species are similar. Thus, no attempt will be made here to address each aspect for every species of interest – only selected individual examples will be given.

Genome Maps

Linkage Maps

Linkage mapping goes back to early stages of classical genetics, including the study of several domestic species. The fundamental principle is that the closer two marker alleles are on a chromosome, the more likely they are to cosegregate during meiosis, i.e., to violate Mendel's second law of independent segregation. However, the paucity of useful monogenic marker polymorphisms (and the difficulty in generating mapping families with multiple polymorphisms) prevented these maps from being of much use in breeding. All this changed with the ability to directly genotype deoxyribonucleic acid (DNA) polymorphisms – changes in DNA sequence (Dodgson *et al.*, 1997). Today, the most commonly used DNA marker is the single nucleotide polymorphism (SNP). The genomes of virtually any two members of any breed (unless highly inbred) typically differ by ~3 million SNPs. Thus, in the extreme case where the genomes of parents and offspring in a segregating family are fully sequenced, an average SNP marker spacing of ~0.001 cM (~1000 bp) theoretically could be obtained. Linkage map resolution no longer depends on marker density but only on the density of meiotic recombinants (i.e., number of informative meioses, which is a function of family size).

Linkage mapping in domestic animals today is most commonly done using SNP arrays. The technology underlying these arrays changes rapidly and depends on manufacturer. In brief, arrays that genotype 50 000 to 600 000 SNPs currently are available for many food animal species (Illumina and Affymetrix being the most common providers). It should be kept in mind that only a subset of the SNPs on the array will be polymorphic in any population of interest. Depending on the objective and the amount of linkage disequilibrium (LD) (a nonrandom association of nearby alleles within a population), smaller and/or custom SNP arrays may be used, for example, to trace genetic relatedness in a closed family where LD remains high. For example, LD has been shown to be higher in white egg layers versus meat-type chickens (Muir *et al.*, 2008) and in thoroughbreds versus other horses (McCue *et al.*, 2012). Custom panels might include only those SNPs that previously have been shown to be informative for a particular population and/or trait of interest. The cost of whole genome sequencing (WGS) (rapidly approaching US$1000 per animal) is nearing that of high density SNP genotyping (~US $300 per animal). However, in many applications, there is little extra value in going from ~300 000 genotyped SNPs to the ~3 million SNPs likely to be revealed by WGS. Occasional applications still exist in which microsatellite markers (Dodgson *et al.*, 1997) are of value. Although microsatellites are much less dense and more cumbersome to genotype than SNPs, they are more polymorphic on a per marker basis, so, for example, a small microsatellite panel may be used to rapidly determine genetic identity or parentage.

There are three major applications of linkage mapping. One is to aid in assembly of genome sequence data, to be discussed later. The second is to locate genetic polymorphisms that affect a phenotype of interest (sometimes referred to as positional cloning, although cloning is no longer required, or QTL mapping). Thus, the goal of linkage mapping is to find the 'disease gene' or the 'QTL gene.' Both of these terms are misnomers, as the same gene exists in both sick and normal or fast- and slow-growing individuals – it is rather their alleles that differ. Note that in many cases, the only identifying characteristic of the trait in question is its phenotype and thus the only way one can find the causal allele in the genome is to observe phenotypic cosegregation with markers. There are two basic approaches. Classic linkage or identity by descent mapping, which involves generating families segregating for the phenotypic traits of interest and genotyping the family as deeply and broadly as possible (Andersson and Georges, 2004; Philip *et al.*, 2011). Association or identity by state analysis, on the other hand, involves comparison of animals that vary in phenotype for correlated allele genotypes at markers that are then presumed to be in LD with the causal allele(s). Association analysis attempts to detect the residual linkage of the causal (or mutant) allele(s) for the phenotype to nearby flanking marker alleles that existed on the chromosome in which the mutation first occurred, despite the historical recombination since the mutation first occurred in the population ancestors. Originally, this was limited to a small number of 'candidate' alleles chosen in genes that seemed likely to be involved (Linville *et al.*, 2001). The advent of dense SNP arrays allows for genome-wide association studies, in which one assumes that at least some of the thousands of SNPs tested will remain in LD with the trait-causing allele (Risch, 2000; Weller and Ron, 2011). Genome-wide association analysis now can also be done using high throughput sequencing (Huang *et al.*, 2010).

The third application uses linkage map markers as surrogates for the trait phenotype or the causal genotype for diagnostic or predictive purposes. In agriculture, this primarily involves using marker information to inform selection decisions during breeding, i.e., marker-assisted selection. Here again, the advent of genome sequences and dense SNP arrays allows for globalizing this approach into genome-wide marker-assisted selection ('genomic selection'; Meuwissen *et al.*, 2001; Goddard *et al.*, 2010). In theory, all the causal alleles (i.e., all of the heritable variation) should be in LD with some of the array SNPs, so once the relationship of the trait to SNP genotype is worked out (by 'training' the model on one or a few generations of phenotyped and genotyped animals), SNP array data could replace the need to measure phenotypes for selection decisions (at least until allele fixation and recombination break down that relationship).

Radiation Hybrid Maps

Linkage mapping aligns markers by the likelihood of cosegregation in the face of meiotic recombination breaks, whereas radiation hybrid (RH) mapping uses the likelihood of cosegregation of genes/markers (into hybrid somatic cell lines) following radiation-induced chromosome fragmentation (**Table 1**). The details (McCarthy, 1996) will not be considered here other than to note that almost any unique gene or sequence element (called a sequence-tagged site (STS)) can be placed on the RH map, and RH maps measure marker distance

Table 1 Types of genome maps

Map type	*Measurement unit*	*Marker binning method*	*Typical resolution in DNA Mb*	*Resolution ultimately limited by*[a]
Linkage	centiMorgan (cM)	Meiotic cosegregation	0.5–5	Mapping population size
Radiation hybrid	centiRay (cR)	Cosegregation upon radiation breakage	0.1–1	Radiation intensity
Cytogenetic	Band location or FLpter	Fluorescence *in situ* hybridization	1	Chromosome spread method
Bacterial artificial chromosome (BAC) contig (a physical map)	kb	Localization to common BAC insert	0.1	BAC insert size

[a]Assuming unlimited marker density.

in centiRays, rather than in centiMorgan (cM) (in both cases, one unit equals 1% probability of breakage). The main advantage of RH mapping is that the required panels are all obtained by cell culture techniques with no need to generate families or populations. However, this means that RH maps are of no use in trait mapping and primarily are employed to aid in assembling either other maps or DNA sequence assemblies. RH maps have been generated for many mammalian species (Lewin *et al.*, 2009) and for chicken (Morisson *et al.*, 2007).

Cytogenetic Maps

Cytogenetic maps place markers (usually genes or large segments of genes) in their locations directly on chromosomes, either with reference to nearby stained 'bands' on the chromosome arms (e.g., 5q11.2 for band 11.2 on the q (long) arm of chromosome 5) or by FLpter value representing the fractional length from the p (short arm) terminus. Today, the most common approach to generating cytogenetic maps involves fluorescence *in situ* hybridization (FISH) (**Figure 1**). Although cytogenetic mapping is labor intensive for whole genome analysis (Cheung *et al.*, 2001), it provides a rapid assay for specific genome aberrations, like major deletions or translocations. Furthermore, it is the only approach to definitively map chromosome structures such as centromeres and telomeres and large tandem-repeated blocks such as ribosomal ribonucleic acid (RNA)-encoding regions (rDNA). Generally, FISH provides relatively low resolution (~1 Mb) but high contiguity (i.e., any two markers on the same chromosome will be detected as such, whereas this may not be possible with linkage or RH mapping when markers are far apart). The resolution of FISH can be improved by employing pachytene-stage meiotic chromosomes rather than mitotic chromosomes or in other ways (Heiskanen *et al.*, 1996). Cytogenetic maps are also very useful for comparative genomics, i.e., identifying genome changes that distinguish two or more evolutionarily related genomes (e.g., Zhang *et al.*, 2011).

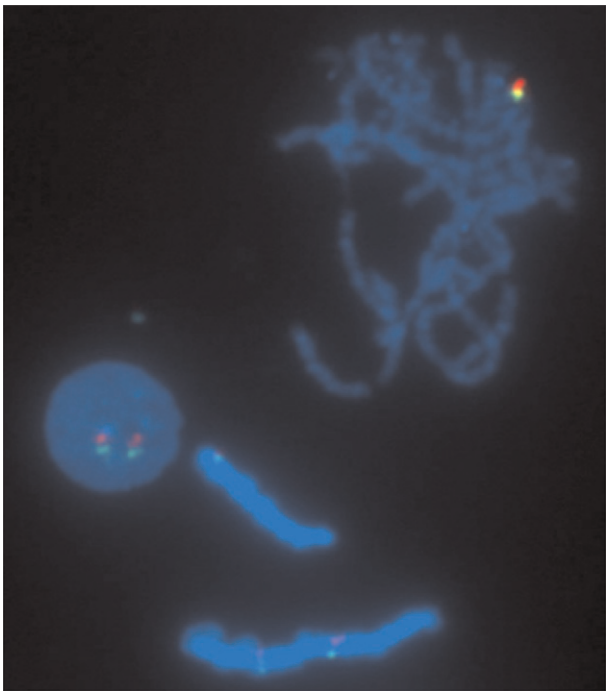

Figure 1 Multicolor fluorescence *in situ* hybridization (FISH). Hybridization of two labeled turkey bacterial artificial chromosome (BAC) clones (110H19, green; 94E20, red) to DNA (blue) of turkey pachytene chromosomes (upper right), an interphase nucleus (left center), and three sperm (bottom center). The two BACs are adjacent in the turkey genome. As the two homologous chromosomes are synapsed at pachytene, only single hybridization signals are found. Methods are as described in Zhang, Zhang, O'Hare, *et al.* (2011). Jiang, Delany and Dodgson, unpublished.

Physical Genome Maps

Although some consider RH and cytogenetic maps to be physical maps, herein this is restricted to maps in which marker separation is a direct measure of DNA length (**Table 1**). The ultimate physical map, then, is the DNA sequence itself, but physical maps also include restriction maps and clone-based contig maps. Recombinant DNA clone-based maps have the advantage that, as part of their generation, the complete genome is divided into clone inserts that then can be used for further molecular analyses. Originally, such maps were believed to be an essential precursor to genome sequencing, but this is no longer the case. The most common form is the bacterial artificial chromosome (BAC) contig map. 'Contig' indicates a continuous segment of the genome that is completely covered by an overlapping collection of cloned inserts (e.g., a BAC contig) or overlapping DNA sequence reads (sequence contig). Most food animal BAC libraries in use were constructed and are available at BACPAC Resources (http://bacpac.chori.org/). Typical BAC libraries have average inserts of 130–180 kb (the larger, the better) and in total span the genome in question ~12 times over (12×coverage). Despite this high redundancy, some sequences cannot be cloned and therefore inevitably result in physical map gaps. The most common approach to assembling BAC contigs is the 'fingerprint' method in which many thousands of BACs are individually digested with one or more restriction enzymes to generate ~50–100 fragments per BAC, and those fragment sizes are measured by gel or capillary electrophoresis (Meyers *et al.*, 2004). The FPC computer program is commonly used to assemble the data into a BAC contig map (Soderlund *et al.*, 2000). The basic principle is that the more the two BAC inserts overlap, the greater the length of common restriction fragments they share. Long repetitive regions and regions of unusually low or unusually high frequency of restriction sites can be problematic for contig building. BAC fingerprint maps have been constructed for many food animal genomes (Wallis *et al.*, 2004; Ng *et al.*, 2005; Humphray *et al.*, 2007; Snelling *et al.*, 2007; Xu *et al.*, 2007; Palti *et al.*, 2009; Zhang *et al.*, 2011). Fingerprint-based BAC contig maps can be augmented by hybridization (**Figure 2**) of unique sequences designed using linkage or RH map markers, comparative maps (see Section Genome Evolution), and from BAC end sequences (BES) (the two ends can be sequenced at high throughput without the need to sequence the full insert). BES are also used to align sequence contigs to the physical map (**Figure 2**). In this way the BAC contig map forms a platform on which the DNA sequence assembly is built (Lewin *et al.*, 2009; Nelson and

Soderlund, 2009). Note that BACs are also used for FISH mapping (Figure 1) to integrate cytogenetic and physical maps, and BES can act as STS probes for RH maps and harbor polymorphisms that can be used to integrate the linkage map as well (Figure 2). Thus, the ideal situation is an interlocking grid of mapping and sequence data that can correct errors or close gaps present in any one assembly.

Reference Genome Assemblies

Methods and Principles

The reference genome sequence assembly and its accuracy are critical to nearly all aspects of modern genomics.

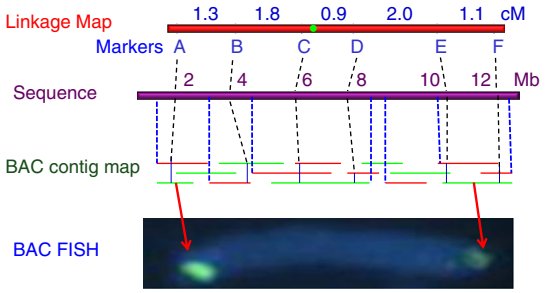

Figure 2 Integration of genome maps and sequence assembly. The linkage map (red) at the top contains six polymorphic sequenced markers ((a)–(f), e.g., single nucleotide polymorphisms (SNPs) within a sequence tagged site) whose intermarker distance is shown in centi Morgan (cM). These markers can be placed uniquely within the DNA sequence assembly (purple line, sequence coordinates shown in Mb from the left end), as shown by connecting black dashed lines. The linkage map can thus be used to align the sequence (Figure 3 for more detail). Linkage markers also can be used as hybridization probes (additional connecting black dashed lines) for alignment with the physical/bacterial artificial chromosome (BAC) contig map (BAC inserts depicted as overlapping narrow red and green lines). The sequence assembly can be aligned using the BAC contig map with BAC end sequences (connecting blue dashed lines) or additional hybridization experiments. The BAC contig map can be aligned with the cytogenetic map using BACs as fluorescence *in situ* hybridization (FISH) probes (red arrows, Figure 1). Similarly, the sequence, linkage, and physical maps can be integrated with radiation hybrid maps using common marker probes (not shown for purposes of clarity).

Sequencing methods (Table 2) change rapidly and space precludes a full description of each. Sanger sequencing is done using one template (usually a recombinant DNA plasmid) in one reaction run on one capillary gel. Typical Sanger reads are highly accurate at least up to 500–800 bases, their maximum length, but certain types of sequence (high GC content and/or inverted repeats) are problematic. Current 'next generation sequencing' (NGS) techniques have much higher throughput, mainly because they employ polymerase chain reaction (PCR) rather than cloning to amplify the signal (sequencing libraries are created directly from genomic DNA), and they are 'multiparallel,' that is, thousands of reactions are run and monitored simultaneously (Shendure and Ji, 2008). Roche/454 has the lowest NGS throughput, but it generates read lengths almost comparable to Sanger sequencing, whereas the others currently give reads in the 35–100 base range. Newer NGS approaches include methods that employ neither PCR nor cloning but sequence single DNA molecules. Nanopore sequencing is just becoming generally available, but offers exciting prospects for the future (Schneider and Dekker, 2012). Most NGS methods have higher error rates per read than Sanger method, but they compensate by higher throughput such that their 'consensus' sequence (average compilation of all reads) may be of comparable accuracy (Metzker, 2010; Glenn, 2011; www.molecularecologist.com/next-gen-fieldguide/).

Given this brief overview, it is important to understand a few general principles of sequence assembly. By itself, the size of vertebrate genomes (haploid size, 1–3 Gb) is no longer a major obstacle. The critical problem is that they contain large numbers of repetitive sequences of varying sizes (1 to $>10\,000$ bp), varying numbers (2 to >1 million copies), and varying locations (Treangen and Salzberg, 2011). Currently, all proven methods (including Sanger) generate read lengths that are shorter than at least some repeats. If long repeats are identical in sequence, or very nearly so, no internal sequence read from one copy can be distinguished from one from a different copy elsewhere in the genome, thus confounding the assembly process. Fortunately, most repeats derive from transposable elements that are no longer active but have replicated during the evolutionary history of the genome, and they have had enough time to diverge in sequence such that the assembler can distinguish them. The longer and more

Table 2 Genome sequencing technologies[a]

Technology or manufacturer	*Type of DNA template sequenced*	*Single read or multiparallel*	*Typical read length (bp)*[a]
Sanger (e.g., ABI 3730)	Recombinant DNA or PCR fragment	Single read	~650
Roche/454	PCR-amplified fragment library	Multiparallel	400–650
Illumina/Solexa	PCR-amplified fragment library	Multiparallel	100–150
Life Tech/ABI SOLiD	PCR-amplified fragment library	Multiparallel	35–75
Life Tech Ion Torrent	PCR-amplified fragment library	Multiparallel	200
Helicos	Single DNA molecules	Multiparallel	35
Pacific Biosciences	Single DNA molecules	Multiparallel	>1000
Complete Genomics[b]	PCR and *Phi*29 amplified library	Multiparallel	35
Oxford Nanopore	Single DNA molecules	Multiparallel	~10 000

[a]Major current commercial providers are listed. Different manufacturers provide multiple instruments with differing specifications. Current estimated typical read lengths are based on manufacturer web sites or the 2012 NGS Field Guide, http://www.molecularecologist.com/next-gen-fieldguide/ (Glenn, 2011).

[b]Complete Genomics provides a sequencing service but does not sell instruments (Drmanac *et al.*, 2010).

accurate any sequence read is, the higher the chance that it can tell one repeat from another and be properly aligned. Repetitive elements are not evenly spread across the genome; they tend to cluster around centromeres and sometimes near telomeres and on the Y- or W-sex chromosomes. The denser the repeats are, the more difficult it is to assemble such regions. This is why centromeres are often left as arbitrary gaps in the assemblies. Similarly, the clusters of rDNA made up of long tandem, near-identical repeats are never fully assembled in the sequence, they are just estimated in size. A related problem is posed by segmental duplications. These are blocks (often large) of DNA repeated a small number of times, most likely due to errors in replication or recombination. They tend to have high sequence identity that confounds the assembly process. Moreover, they are polymorphic in existing populations, so the sequenced 'reference' animal's genome may differ from that of any other animal of interest. A common situation is that reference sequence assemblies will 'over-collapse' segmental duplications (especially those that are nearby one another). For example, earlier versions of the chicken genome sequence included only a single interferon alpha (*IFNA3*) gene, whereas the current (Gallus_gallus-4.0) version, based on ordered sequencing (see below) of the chicken Z-chromosome by Bellott *et al.* (2010), contains the previously known number of ten linked copies (Sick *et al.*, 1996).

Almost all food animal reference genomes (**Table 3**) are based on sequencing a single, individual animal. These animals are diploid, of course, and at best only partially inbred, so their genomes retain allelic diversity in some locations (certain aquaculture species can avoid this problem, *see* Davidson *et al.*, 2010). When the sequence assembly program sees two different sequences that are, for example, 99% similar, it may interpret these as a segmental duplication and build two copies of that sequence into the reference, when in fact these represent two alleles of the same single copy sequence (Kelley and Salzberg, 2010). For example, even though a substantially inbred animal was used for the chicken genome sequence (International Chicken Genome Sequencing Consortium, 2004), 17 Mb of erroneous duplicated sequences were present in earlier versions (removed in the Gallus_gallus-4.0 assembly). All food animal genomes are considered 'draft' sequences denoting their incomplete and occasionally inaccurate nature, but the quality of draft sequences spans a wide range. Even though the human genome has been intensively studied and is considered a 'finished' sequence, it still contains some gaps and errors and is continually being updated (Church *et al.*, 2011).

Table 3 Example food animal reference genome sequence assemblies[a]

Species	*Assembly*[b]	*Method*[c]	*Sequenced bases (Gb)*[d]	*Scaffold number*	*Scaffold N50 (Mb)*	*Contig number*	*Contig N50 (kb)*
Cow[e]	Btau_4.6.1 October 2011	Shotgun Sanger	2.983	13 387	2.60	81 416	83.7

[a]Statistics from NCBI Assembly, http://www.ncbi.nlm.nih.gov/assembly, accessed June 28, 2012.
[b]Assembly names are from the UCSC browser (http://genome.ucsc.edu), where available, or NCBI Assembly.
[c]Predominant method used, although supplemented by alternative approaches. For example, the chicken Z chromosome has been sequenced by ordered sequencing (Bellott *et al.*, 2010).
[d]These assemblies are 90–95% complete; multiply sequenced bases by 1.05 to 1.1 for haploid genome sizes.
[e]There are two comparable cow assemblies using much the same data but different assemblers.
[f]The bird that was sequenced was a red junglefowl, the nearest wild progenitor of chickens.
[g]The Atlantic salmon contigs are yet to be joined into scaffolds.

Reference genome sequences are assembled as various combinations of two basic approaches (Table 3): the ordered or 'BAC by BAC' approach versus the whole genome approach first proposed by Venter *et al.* (1996). The ordered approach requires that one first assemble a high quality BAC contig physical map. One then sequences the fewest possible BACs that together most fully cover the genome, one at a time. The advantage of the ordered approach is that assembling the sequence of the 100–200 kb insert in a single BAC is much easier and more accurate because the computer, on average, deals with approximately 0.01% of the number of repeats in the total genome. The disadvantage, especially in today's world of NGS, is that the cost and effort required to generate the BAC map far exceeds that required for bulk sequencing. Examples of ordered genome sequences include maize (Schnable *et al.*, 2009), the chicken Z-chromosome (Bellott *et al.*, 2010), and partially that of swine (Groenen *et al.*, 2012). In the first two instances, ordered sequencing was chosen due to a very high density of repetitive elements. For the swine genome, the decision was driven, in part, by the preexisting availability of a very high quality BAC contig physical map (Humphray *et al.*, 2007).

Most genomes today are sequenced either solely by shotgun methods or with a hybrid approach (Green, 2001), primarily with shotgun reads but with the added use of BAC contig maps to assist in assembly and alignment to chromosomes. A limited number of BACs are often sequenced one at a time as a reference to judge assembly accuracy. The key tool for accurate shotgun assembly is the 'mate pair' or 'end pair' (Figure 3). Most animal genomes are collections of tens of thousands (or more) sequence contigs (Table 3) that typically range in size from approximately 1 kb to 1 Mb. These pieces of the linear genome jigsaw puzzle are aligned into 'scaffolds' with mate pairs, sequences from opposite ends of fragments whose approximate size is known. Typically, a genome sequencing project will include libraries of mate pair fragments of different sizes, for example, 3 kb, 10 kb, and 50 kb. Assembly programs align the two mate pair reads (with appropriate orientation) assuming that they are the distance apart indicated by the fragment library size. For example, if there were two 500 bp mate pair sequences from a 3 kb fragment, the assembler assumes that there is a 2 kb gap between the two. Obviously, the accuracy of the estimated gap size depends on how narrow is the library fragment size distribution. For Sanger sequencing, the libraries are recombinant clone libraries, whereas the various NGS sequencers each have methods to obtain end-pair reads from size-selected DNAs. The sequence assembler uses mate pair sequences (usually requiring at least two to prevent 'false joins') to align adjacent sequence contigs and estimate the gap size. Collections of sequence contigs are called scaffolds (Figure 3). Gaps remaining between scaffolds not spanned by mate pairs are likely to be larger (and/or problematic due to repetitive sequence). Generally, there will be thousands of scaffolds in a draft genome. (The numbers and average sizes of contigs and scaffolds are usually dominated by a preponderance of small fragments, for example, unplaced 'singletons' that overlap nothing else. Thus, the preferred measure of assembly quality is the N50, which is the smallest contig or scaffold such that 50% of the genome is covered by it and all larger contigs or scaffolds, Table 3.) In any good quality-assembled genome, many scaffolds will be large enough to contain multiple physical map, RH map, or linkage map markers. Those maps can then be used to align scaffold order and identify the appropriate chromosome from which they are derived (Figure 3). This results in 'superscaffolds' that often are melded into a full chromosome-sized 'pseudomolecule,' with numerous gaps connected by Ns (unknown bases), usually including a large, poorly estimated gap at the centromere.

Table 3 indicates the current status of several food animal genomes. Many of these were generated primarily, if not solely,

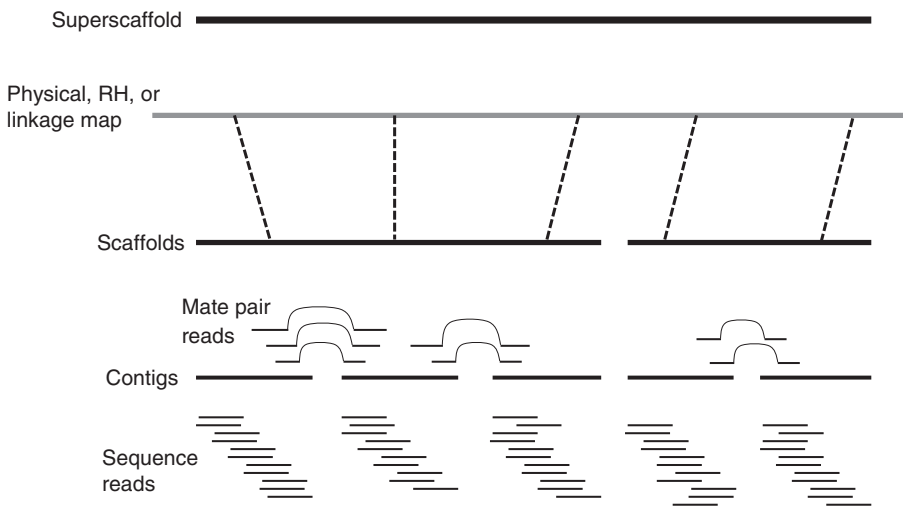

Figure 3 Sequence assembly from shotgun sequence reads. Overlapping sequence reads at the bottom are assembled into sequence contigs. Mate pair reads with one end in each of two contigs and an estimated total size are used to align adjacent contigs and estimate gap size. Contigs joined by mate pairs form scaffolds (in this example, mate pairs join the first three contigs into one scaffold and the last two into another scaffold). Dashed lines indicate sequence segments that can also be located on a physical map (bacterial artificial chromosome (BAC) end sequences or hybridization probes), a radiation hybrid (RH) map (sequence-tagged site (STS) markers), or a linkage map (polymorphic markers, e.g., single nucleotide polymorphism (SNP)). These are used to orient and align scaffolds into superscaffolds (top line).

with Sanger sequencing, although all have been, or will be, supplemented with additional NGS reads. The turkey genome (Dalloul *et al.*, 2010) likely set the stage for the future in that it was solely assembled from NGS reads but with the adjunct of dense BAC contig and linkage maps to aid in alignment. There often is a considerable time gap between the initial 'release' (**Table 3**) of a genome sequence and its annotation and availability on genome browsers (described next).

Genome Annotation

By itself, the reference genome sequence is of limited utility to much of the user community, with its ultimate value depending on proper annotation (Yandell and Ence, 2012). In its widest sense, annotation means linking the DNA sequence to all the information available on genes, messenger RNAs (mRNAs), proteins, etc. This ideal is never realized, but because much of that information is linked via a gene name, the first, and most critical, step is locating and appropriately naming all of the genes (encoding both proteins and noncoding RNAs (ncRNAs)). Once the genome is sequenced, there are two methods to find the genes – both of these are, at least initially, done by a computer (see Yandell and Ence, 2012), although they can be improved by subsequent manual curation. The first is evidence based – this primarily uses cDNA (complementary DNA, that is, DNA copied from a mRNA) clone sequences (often called expressed sequence tags (ESTs)) and other transcriptomic or proteomic (see below) data, as well as homology to known genes in other species. At least for mammalian food animal species, comparisons to the very well annotated human and mouse genomes are especially powerful. (However, keep in mind that those aspects of animal physiology most relevant to agricultural utility may tend to be among the least likely to have direct counterparts in humans or mice, e.g., wool production in sheep.) The second general method to identify genes involves *ab initio* annotation. In this case the program searches for open reading frames, likely initiation and stop codons, splice junctions, and other sequence-based characteristics to predict the existence of genes for which no experimental evidence is available. Some of these programs (e.g., Genscan) are first 'trained' on a set of strongly supported, evidence-based genes. *Ab initio* annotation is more successful at predicting protein-coding genes than ncRNA genes (the latter are predicted on the basis of characteristic secondary structures). Transposable elements can be annotated on the basis of their repetition in the genome, relatedness to transposons in other species, and their characteristic end structures (Jurka *et al.*, 2005). Annotating regulatory sequences (such as transcription factor-binding sites) is more problematic, but accuracy can be improved if one can employ a cluster of evolutionarily related genomes and use purifying selection among the identification criteria (e.g., Stark *et al.*, 2007). The human ENCODE project (The ENCODE Project Consortium, 2012) has made extensive and detailed observations at specific sequence regions to understand what characteristics are of critical importance, and such data have improved annotation substantially, especially for regulatory sequences.

Most food animal species genomes reliably can be expected to contain 20–30 000 protein-coding genes, as do those of most vertebrates (there may be more in species such as salmonids that have gone through a recent genome duplication, Davidson *et al.*, 2010). As more mRNA sequence data accumulate (see Section Transcriptomics) from more and more tissues, it should be possible to find some evidence to support virtually all functional genes. (Even now, one tends to distrust *ab initio* predictions for which there is no supporting RNA or homology evidence.) However, an important problem for annotation is that what might naïvely be described using a single gene name, in fact, encodes many different transcripts due to alternative transcription start sites (TSS), transcription termination sites (TTS), and splicing patterns. Many, and probably most, genes exhibit some of these alternatives, the functional significance of which remains to be worked out in most instances. Alternative TTS and TSS are nearly ubiquitous, but many of these do not alter the encoded protein sequence, whereas alternative splicing often does. The various possible transcripts for a given locus may be described as different 'gene models.' It is nearly impossible for *ab initio* methods to accurately annotate a set of transcripts. Even with high throughput RNA sequence data, it can be challenging to estimate which of several possible combinations of TSS, TTS, and exons are employed by the cell without detailed gene by gene molecular analysis.

Genome Browsers

The interface for most of the user community with reference sequences is provided by a genome browser. There are three major browsers: University of California at Santa Cruz (UCSC) Genome Bioinformatics (www.genome.ucsc.edu), Ensembl (www.ensembl.org), and the National Center for Biotechnology Information (NCBI) Map Viewer (http://www.ncbi.nlm.nih.gov/genome), each of which has its own unique characteristics and options. There are also a variety of species-specific genome browsers (e.g., BovineGenome.org) that often contain additional information of interest. (See http://www.animalgenome.org/ for updated lists of relevant links for food animal genomics.) One begins by finding the genome browser gateway and choosing the species and the sequence build of interest. (Note that sequence coordinates change from one build to another as do the available annotation tracks, see the paragraph below.)

The browsers all employ the same reference sequence information as a series of linear sequences, usually chromosome-specific 'pseudomolecules,' but sometimes just a list of scaffolds that are yet to be aligned to chromosomes (or both). The presence or relative intensity of any characteristic (exons, %GC, depth of transcription, homology with other sequences, etc.) that can be mapped on the sequence can be displayed as a 'track' on the genome. The user controls the tracks displayed (**Figure 4**), their format and order, and can also submit their own data for either private or public access as additional tracks. Each build of a genome will have its own available track annotations, not all of which may be available on another build. It is not possible here to begin to summarize the various options and datasets available; however help and tutorials are provided at each site. The most common use of browsers is probably to view genes, gene models, repetitive elements, transcription data, and homology/conservation evidence (**Figure 4**).

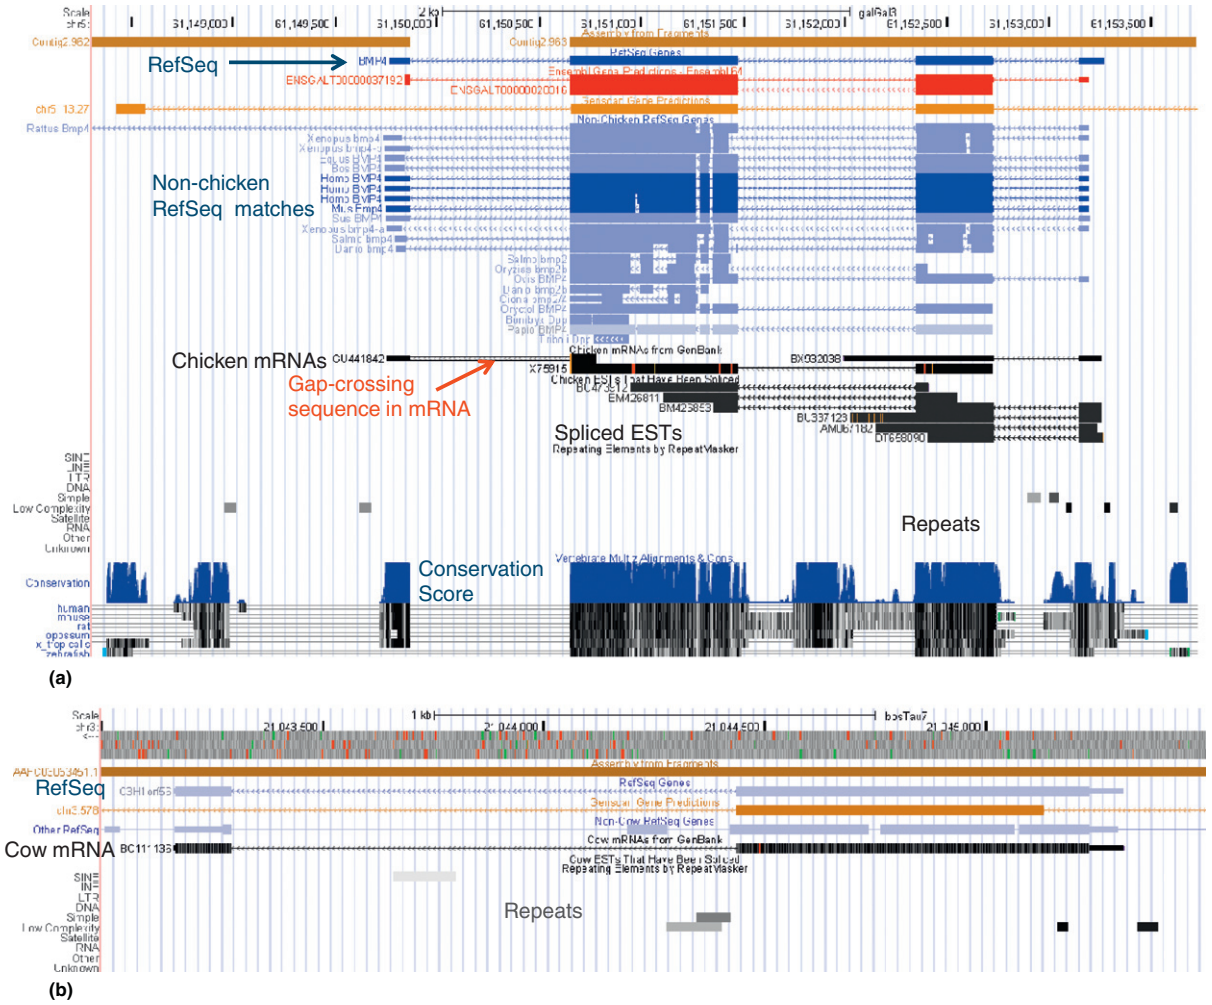

Figure 4 Example uses of UCSC genome browser. (a) The chicken *BMP4* gene from the (May 2006) Gallus_gallus-2.1 assembly. *BMP4* is transcribed right to left. Thick brown lines below sequence coordinates depict the two sequence contigs in this region. Below it, top to bottom, are the RefSeq gene model (blue arrow), two different Ensembl gene models (dark red), the *ab initio* Genscan model (light brown, note incorrect exons at both ends), homology to nonchicken RefSeq genes (various shades of blue), and sequence mapping to 'chicken mRNAs' and to spliced expressed sequence tags (ESTs) (black). Exons are shown as boxes with coding regions thicker than untranslated regions (UTRs); introns are depicted as narrow lines with arrowheads in the direction of transcription. Chicken mRNAs are cDNA clone sequences entered into Genbank as full length, but often (as shown here) they are not. ESTs are single pass partial cDNA sequences – spliced ESTs are more reliable, so only those are shown here. This gene has an exon that crosses the gap region whose sequence can be inferred from the sequence of the mRNA marked with a red arrow. (The gap is estimated to be 790 bp in the assembly but actually is 129 bp.) At the bottom are shown various repeat sequences (gray blocks, only a few simple or low complexity repeats are found) and a blue 'wiggle' plot depicting the (multispecies) Multiz evolutionary conservation score of the chicken sequence (usually highest near exons) with homology to individual genomes below this as mostly gray tracks. This view was generated with track settings: Base Position – full, Assembly – pack, RefSeq Genes – pack, Other RefSeq – pack, Ensembl Genes – pack, Genscan Genes – pack, Chicken mRNAs – pack, Spliced ESTs – pack, Conservation – pack, and RepeatMasker – full. All other tracks were set to hide. The UCSC Genome Browser Gateway at http://genome.ucsc.edu was accessed on 29 June 2012 (Kent *et al.*, 2002). (b) The cow *C3H1orf56* gene from the Btau_4.6.1 assembly is transcribed right to left. This is the cow ortholog of an anonymous human gene named *H1orf56* to indicate open reading frame 56 on human chromosome 1. The ortholog is on cow chromosome 3, so the name is changed to *C3H1orf56* to indicate both its chromosome in cattle and in human. At this magnification level, the Base Position (gray) tracks at the top show all three reading frames, here set to show the negative (right to left) strand. Green and red tick marks indicate methionine and stop codons, respectively. The bottom frame is used (no stops) for exon 1 and the top frame is used for exon 2 by *C3H1orf56*. This region is covered by a single contig (long brown bar at top), below which are shown the cow RefSeq gene (light blue), the Genscan prediction (light brown, highly inaccurate), homology to noncow RefSeq genes (light blue, dense version, so all of these are compacted into one line), the single cow mRNA in Genbank (black) and repetitive elements detected by RepeatMasker. (Ensembl gene predictions are not currently available.) Exons are depicted as boxes, thicker for coding regions, and introns as lines with arrowheads depicting transcription direction. This view was generated with track settings: Base Position and RepeatMasker set to full; Assembly, RefSeq Genes, Genscan Genes, Cow mRNAs, Spliced ESTs (there are none) all set to pack; and other RefSeq set to dense. All other tracks were set to hide. The UCSC Genome Browser Gateway at http://genome.ucsc.edu was accessed on 29 June 2012. Kent, W.J., Sugnet, C.W., Furey, T.S., *et al.*, 2002. The human genome browser at UCSC. Genome Research 12, 996–1006.

The browser offers a variety of gene model outcomes (depending on the tracks displayed, Figure 4). The most reliable are the RefSeq genes that have been manually annotated by NCBI, but the RefSeq set is conservative (i.e., low false positive and high false negative rate). Ensembl gene predictions (and UCSC, where available) detect most (but not all) genes in a vertebrate genome and provide more possible models per coding locus but with more false positives. Each gene predictor may fail to specifically name a gene of interest, giving it instead an anonymous LOCxxxxxx (or ENSxxxxxxxxxxxx) name, even when it may be easy to deduce the proper name by manual curation. For the great majority of food animal genes, the species nomenclature defers to the human gene nomenclature, so the name of the nearest homologue in human is also the name in, for example, cow (see an exception in Figure 4(b)). If there is a single copy of the gene in both species (called 1:1 orthologs), then the proper name is obvious. When there are 5 copies of closely related genes in human and 8 in cow, things can get tricky (e.g., the current human assembly annotates *NOS1*, *NOS2*, and *NOS3* genes, the bovine genome only *NOS2* and *NOS3*, and the chicken only *NOS2*, although it contains currently unannotated *NOS* sequences, probably *NOS1* and *NOS3*). Usually, the most homologous (most similar in sequence) pair of genes between the two species are considered orthologs and other possible pairs are paralogs (see Glossary for the strict definition). The orthologous gene pair members should have the same name. Another way to identify orthologous pairs employs conserved gene order. Vertebrate genomes, especially those of amniotes (mammals and birds), tend to have reasonably long segments in which genes are aligned in the same order and direction. For example, assume there are two related human gene family members, B1 and B2, and cow gene X exhibits similar sequence homology to both B1 and B2. If gene order in human is A – B1 – C on one chromosome with M – B2 – N on another, and cow gene X is between cow M and N, then it is likely to be the cow B2 gene.

Genome browsers are only as good as the underlying sequence assembly and annotation. The problem of assemblers 'overcollapsing' repeated sequences and segmental duplications already has been discussed. As shown in Figure 4, gene models (Ensembl, Genscan, etc.) should always be treated with caution. Automated gene predictors will often try to place missing exons in whatever sequence exists rather than in a gap between contigs where they really should be. (The correct exon sometimes can be determined from mRNA or EST sequences corresponding to the gene in question, Figure 4(a).) For those species with good EST collections (true for many food animals), the ESTs (or RNA-seq data, see Section Transcriptomics) are often the most reliable predictors of the true gene models. In addition, gene predictors may fail where homology between the gene and its orthologs in other species is low, especially, but not solely, in 5′ and 3′ untranslated regions (UTRs). Genes that are large and/or have limited transcriptional evidence may be split into two or more gene models; conversely, programs sometimes merge two adjacent genes (transcribed in the same direction) into one long gene model. Gene prediction programs are very poor at accurately annotating 5′UTRs and especially 3′UTRs, in part because of the diversity of alternative TSS and TTS discussed previously.

Resequencing Genomes

Mutant Analysis

The availability of a reference genome sequence enables rapid 'resequencing' of any animal genome using NGS. Resequencing is much easier than *de novo* sequencing because one only has to align all the reads with the preassembled reference (using one of several programs designed for the purpose such as BLAST, Altschul *et al.*, 1990). Indeed, some resequencing methods only work by mapping to a reference; they cannot do *de novo* assembly. The goal is to ascertain where and how the genome being resequenced differs from the reference. These differences typically will include millions of SNP polymorphisms, 100 000 or more small indels and possibly hundreds of differences in segmental duplications (also called copy number variations), or rare large-scale rearrangements. Furthermore, even if resequencing is 99.99% accurate, there would be 300 000 errors in a mammalian-sized genome, plus any errors remaining in the reference sequence itself (NGS manufacturers report 99.99% accuracy in consensus high coverage reads, but coverage levels across the genome are variable and some regions are more error prone.) How do we find needles in this haystack?

First consider a situation in which a trait of interest is due to a single mutation at one site in the genome and the comparison is made between the mutant genome sequence and a reference genome or that of a nonmutant relative. The first choice is between whole genome sequencing (WGS) and 'exome' sequencing. Exome sequencing uses an array of synthetic oligonucleotides (see Section Transcriptomics) to hybridize to and enrich the target genome DNA for only those sequences in exons. (Similarly, if your mutation of interest is already mapped to a segment of the genome, you can enrich for just that region, Charlier *et al.*, 2008; Robb and Delany, 2012.) Exons make up less than 2% of a typical mammalian genome, so if exome enrichment were perfect, coverage would increase by ~50-fold. Increased NGS coverage translates to increased accuracy; important when searching for a single causal mutation in a potentially large background of errors and polymorphisms. Despite the significant challenges posed by background diversity and errors, exome sequencing is now being widely applied in medical genetics (Gonzaga-Jauregui *et al.*, 2012). Obviously, if the causal mutation lies outside of an exon, exome sequencing will not work. WGS can be used, but filters must be applied to narrow the search. As an example, Roach *et al.* (2010) used WGS (Complete Genomics) of a quartet (both parents and two children) in which both children suffered from the same two rare inherited diseases. By focusing only on coding regions within the 22% of the genome inherited identically by both children and assuming that the causal alleles must be rare (i.e., ruling out all variants already within the large and rapidly growing human SNP database), the authors were able to narrow candidate disease-causing mutations to four genes, two of which were confirmed by other studies.

Diversity Analysis and Signatures of Selection

Resequencing is more commonly used in food animals to sample existing genetic diversity within breeds, commercial

lines, or the domesticated species as a whole. First, this provides data for the design of high-density SNP arrays previously discussed (Matukumalli *et al.*, 2009; Ramos *et al.*, 2009; Groenen *et al.*, 2011; Liu *et al.*, 2011; McCue *et al.*, 2012). As noted above, NGS costs are now approaching a level at which WGS and high-density SNP genotyping applications are merging. For example, both WGS and high-density SNP typing allow one to estimate worldwide breed diversity and the history of domestication and selection that led to their current state (Muir *et al.*, 2008; Bovine HapMap Consortium, 2009; Kijas *et al.*, 2009; Kijas *et al.*, 2012; McCue *et al.*, 2012). Such studies also document genomic features related to recombination rate and its inverse, LD (International Chicken Polymorphism Map Consortium, 2004; Groenen *et al.*, 2009; Megens *et al.*, 2009). For example, Auton *et al.* (2012) recently generated a fine-scale recombination map for chimpanzee by sequencing only 10 animals. Of particular interest for food animals is the search for selective sweeps, regions of unusually high LD due to intense selection during domestication or later breeding for an allele that has a major effect on a desirable trait (Bovine HapMap Consortium, 2009; Rubin *et al.*, 2010; Moradi *et al.*, 2012) which again can be done either by resequencing or high density SNP genotyping. Note that in detecting a selective sweep, one identifies a common distribution at many linked SNPs within a segment of the genome on the order of 10–100 kb or larger. Thus, such an analysis is much more robust than identifying a single point mutation and can more easily tolerate the background error rate of NGS.

Comparative Genomics

Genome Evolution

Comparative genomics refers to the alignment of genes and sequences between species either to draw inferences as to how their genomes evolved or to compare and contrast genetic mechanisms. Comparative genomics is especially important in food animal species because it provides connections to aspects of genetics and physiology that sometimes are better studied in humans (e.g., medical genetics) or 'model' species such as mouse and zebrafish. The previously described development of DNA-based markers allowed for alignment of genome maps across multiple species (O'Brien *et al.*, 1988; Nadeau, 1989) at much greater resolution than did previous linkage and cytogenetic maps. Because exon sequences of most genes are evolutionarily conserved, gene-based maps could be aligned between species whose last common ancestor lived hundreds of millions of years ago. For example, long segments of bird and mammalian gene alignments have been conserved for >300 million years of separate evolution (Burt *et al.*, 1999; Suchyta *et al.*, 2001), despite the fact that avian genomes are only approximately a third the size of those of mammals. The clear implication is that introns and intergenic sequences can expand or contract greatly (most often through insertion and removal of transposable elements) over evolutionary time, whereas the chromosomal order of genes remains largely preserved. This is the basis for the use of conserved gene order to infer orthologous gene pairs as described above, and it probably reflects the fact that large chromosome rearrangements can severely reduce reproductive fitness. The most common rearrangements that have occurred during evolutionary history seem to be inversions within a single chromosome rather than translocations between two different chromosomes (e.g., Zhang *et al.*, 2011).

Sequence Evolution

The advent of whole genome reference assemblies allows for full sequence alignment of genomes between species along individual chromosomes. Obviously, such alignments are much more fine grained than chromosome or gene order-based alignments (**Figure 5**). The questions addressed differ depending on the pair (or group) of genomes chosen. For example, aligning the recently diverged human and chimpanzee genomes (Chimpanzee Sequencing and Analysis Consortium, 2005) will generate high (>90%) levels of homology across almost the entire genome. The focus then is on the relatively rare differences between the two and what differences in human and chimp biology they might explain. However, aligning the widely divergent human and chicken genomes (International Chicken Genome Sequencing Consortium, 2004) gives only short, discontinuous blocks of similarity (bottom of **Figure 4(a)**) separated by long regions with no more than random homology. In this case, one examines what is similar between the two genomes and what that might tell us. Indeed, a primary rationale for National Institutes of Health financial support for sequencing the chicken genome was that one could clearly detect sequences under long-term evolutionary selection because the background similarity between neutrally evolving sequences is nonexistent. The outcome was that approximately 2.5% of the human genome (~7% of chicken) appears to have been under selective pressure over their 300 million years of separate evolution (International Chicken Genome Sequencing Consortium, 2004). Because only approximately half of this encodes proteins, a major question remains as to what the function of the rest might be (Lindblad-Toh *et al.*, 2011; The ENCODE Project Consortium, 2012). Alignment of related genome sequences provides a powerful tool for detecting and annotating sequences that are of functional importance, especially in nonprotein coding regions (Stark *et al.*, 2007; Lindblad-Toh *et al.*, 2011; Lowe *et al.*, 2011). As many more vertebrate genomes are expected to be sequenced in the next few years (Genome 10K Community of Scientists, 2009), the power of comparative sequence analysis to explore the biology of food animals should grow rapidly.

Transcriptomics

Microarrays and RNA-seq

Full genome reference sequences lead to predictions of ~20 000 genes (potentially 100,000 or more transcripts). Having this in hand allows for global measurements of RNA (usually mRNA) expression, the domain of transcriptomics. Originally, these analyses employed microarrays typically containing 10 000 to 1 million elements. Each element contains a unique DNA hybridization probe (usually 25–50

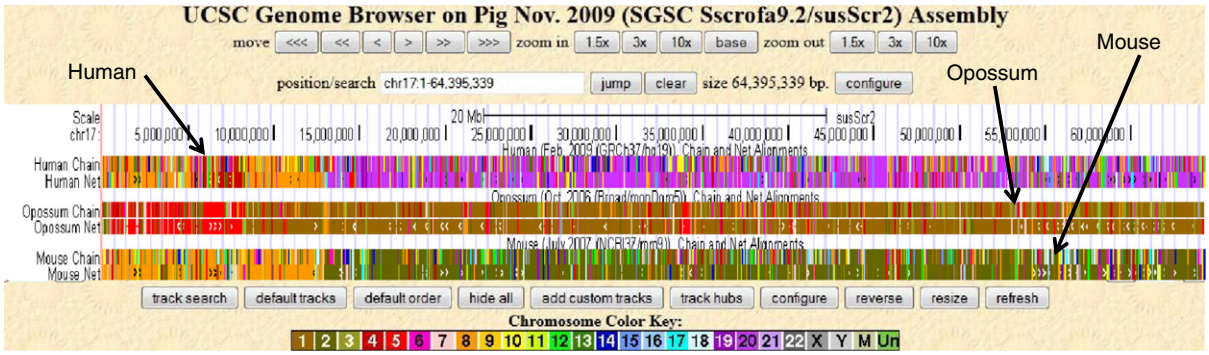

Figure 5 Comparative maps. The full length (64 395 339 bp) of swine chromosome 17 (SSC17) is shown with paired tracks matched to the human, opossum (*Monodelphis domestica*), and mouse genome sequences. (The two tracks, Chain and Net, use different parameters for the alignment with the Chain version being somewhat more finely grained.) Using the color key at the bottom, it can be seen that SSC17 consists primarily of two blocks of homology to the human genome, the first homologous to HSA8 and the second to HSA20, with the junction between the two at approximately 13 Mb. The same two blocks are observed by comparison to the mouse genome with the first block being homologous to MMU8 and the second to MMU2. Two major homology blocks are also observed by comparison of SSC17 to the genome of the more distantly related marsupial, *M. domestica*, but the breakpoint is different, close to 8.2 Mb. Note that there are frequent small blocks where the region of greatest homology differs from these overall trends. These are unlikely to be due to chromosomal rearrangements (translocations) that occurred during mammalian evolution and are more likely due to transposition (e.g., transposable element movements) or fortuitous matches to paralogous rather than orthologous members of multigene families. This view was generated with track settings: Base Position – full, Human Chain/Net – squish, Mouse Chain/Net – dense, and Opossum Chain/Net – dense. All other tracks were set to hide. The UCSC Genome Browser Gateway at http://genome.ucsc.edu was accessed on 29 June 2012. Kent, W.J., Sugnet, C.W., Furey, T.S., *et al.*, 2002. The human genome browser at UCSC. Genome Research 12, 996–1006.

nucleotides) designed using the predicted exons. Although there are technological differences between the available platforms, it is generally found that they generate similar relative gene expression profiles (Chen *et al.*, 2007; Li *et al.*, 2009). Transcriptomics involves the isolation of mRNA from multiple cells, tissues, and/or individuals, typically after different treatment regimens (e.g., pathogen infection, drug treatment, and diet) and/or at different developmental times. The mRNA sequences are converted to cDNA (or cRNA), then labeled, and finally hybridized to arrays, followed by washing and label quantification. In some cases, experiments simultaneously hybridize two differently labeled probes, providing an internal control (e.g., posttreatment vs. pretreatment). Alternatively, the Affymetrix platform averages the intensity ratio of multiple experimental probes per gene to that of control probes that contain a designed mismatch to the target sequence.

Decreased NGS costs have led to sequence-based transcriptomics technology, called RNA-seq (Wang *et al.*, 2009), in which high throughput short sequence reads are made from cDNA copied from (fragmented) mRNA (or other types of RNA). The measure of gene expression is digital (the number of times one obtains a give unique sequence) rather than analog (fluorescence intensity on a microarray). RNA-seq reads are often mapped to a reference genome and expressed in reads per kb per million mapped reads or an equivalent measure. Although RNA-seq remains a bit more expensive than microarrays, it offers the advantage that the expression of any unique sequence in the reference genome can be measured (not just what is probed on an array), and sequence reads have single base resolution, so two alleles (or two repeats) that differ by a single base in a mapped read can potentially be distinguished (Malone and Oliver, 2011). Microarray data usually give a single averaged measurement per gene per sample, whereas RNA-seq data are often used to detect differential expression of exons within a gene (due to alternative TSS, TTS, and splice sites) and can directly be mapped to predicted splice junctions and/or poly (A) termini (e.g., Pickrell *et al.*, 2010). Both techniques generate a list of hundreds to thousands of genes (or exons) with a measure of their expression (or differential expression relative to a control) for each experimental sample.

The question of how to treat these huge datasets is nontrivial. What is a significant change in gene expression? At first, an arbitrary criterion, such as a twofold or greater difference, was often employed. Of course, the proper way to address statistical significance is to repeat the experiment many times and determine confidence intervals, but this is often too costly for microarray and RNA-seq analyses. RNA-seq gives an integral number of observations of any given read that can be directly translated to a *p*-value, and more sophisticated methods of handling microarray data also have been developed. As with so many aspects of genomics, one must also correct for the multiple hypothesis testing problem in some fashion (Cheng and Pounds, 2007). Beyond simple significance, are questions of sorting and interpreting the results. Typically, one is dealing with a two-dimensional matrix in which one dimension is the number of genes under study and the other dimension is the number of expression measurements for each gene (time points, dosages, diets, etc.). A common approach to dealing with the data matrix is hierarchical clustering (Eisen *et al.*, 1998) which basically aligns each gene in a linear order such that its expression profile differs least from its nearest neighbors in a local cluster. A dendrogram can be drawn that, like an evolutionary phylogeny, connects the clusters (clades) with the distance

along the dendrogram connecting any pair of genes being proportional to their difference in expression pattern. Other approaches such as k-means clustering and self-organizing maps (Sherlock, 2000) are available that can group the genes into a predetermined number of clusters. These methods are of particular value for imputing the function of otherwise unknown genes, because one expects that the unknown will cluster with known genes of similar function.

Another mechanism by which any list of genes can be connected to functional information is via Gene Ontology (GO) annotation. GO is a 'controlled vocabulary of terms for describing gene product characteristics and gene product annotation data' (http://www.geneontology.org/). Genes are described in terms of the biological processes in which they participate, the cellular components in which the encoded protein is found, and its molecular function. These overarching categories are subdivided into more narrow and specific terms in a hierarchical fashion. Genes of known function (at least partially known in some species) have been annotated within the appropriate categories or term associations. For example, histone H5, an avian variant of the histone H1 type, is associated with chromosome condensation and nucleosome assembly under biological process; with Golgi apparatus, nuclear chromatin, and nucleosome under cellular component; and with DNA binding under molecular function. Bovine beta casein is associated with regulation of blood pressure under biological process; extracellular region under cellular component; and antioxidant activity, metalloendopeptidase inhibitor activity, protein binding, and transporter activity under molecular function. GO analysis of a list of genes (such as would be obtained from a microarray study) counts the number of genes in the list that fall into each of the GO term associations. Statistical analysis determines if the gene list was 'enriched' for that category, i.e., exhibited significantly more genes with that association than the random expectation. Thus, if a list of genes that were upregulated in cattle placed on a high-fat diet was analyzed, enrichment for terms such as adipose tissue development, fat cell accumulation, fat cell differentiation, white fat cell proliferation, etc. might have been found. The connection between diet and GO term would be obvious in this case, but interesting and unexpected connections do arise that can generate hypotheses for further testing. Another popular approach is to do pathway (or network) analysis of a microarray or RNA-seq gene list. As with GO analysis, the gene list will be searched for enrichment (vs. random expectation) for genes known to function in a particular metabolic or physiological pathway (or a previously determined network of interacting genes, see below). A popular site for pathway analysis is the Kyoto Encyclopedia of Genes and Genomes (http://www.genome.jp/kegg/).

Others may disagree, but this author's opinion is that, to date, transcriptomic studies in food animals have failed to generate novel or transformative biological insights in proportion to the effort and cost expended. In part, this is due to the incomplete annotation of animal genomes. Automated annotation of the reference genome is used to design probes for microarrays and to analyze the data produced by either arrays or RNA-seq. If a substantial number of genes or exons are inaccurately annotated or are given anonymous gene designations, the power of any downstream analysis of transcriptome data will be reduced. A larger problem is our very incomplete understanding of function and relation to phenotype for most genes. For example, sequence homology might suggest that a certain gene encodes a protein kinase that functions in cell–cell signaling. At least in model species, some of the proteins that this kinase phosphorylates might be known, but this fails to provide a full understanding of how polymorphic variations in the gene sequence translate into complex phenotypes. This is especially true for the phenotypes that are of particular relevance to agriculture (e.g., feed conversion efficiency, egg production, and susceptibility to pathogens). Finally, there is the fundamental question of how well mRNA levels reflect ultimate gene function. For example, von Merling *et al.* (2003) found that correlation of mRNA levels (coexpression) was a rather poor predictor of proteins that interacted with one another or functioned in a common pathway. One assumes that most mRNAs exert their effect through the proteins they encode, and global mRNA–protein level correlations (r^2) have generally been found to be approximately 40% at best (de Souza Abreu *et al.*, 2009; Maier *et al.*, 2009; Vogel *et al.*, 2010; Schwanhäusser *et al.*, 2011). This would seem to set an upper limit on the extent to which mRNA level measurements could explain cellular, let alone organismal, phenotypes.

eQTLs

The level of mRNA expression for a given gene in a given condition is a quantitative trait in the same sense that egg production or backfat thickness might be, and in any segregating population, it should be possible to map the genetic polymorphisms that influence each gene's expression, an approach sometimes called 'genetical genomics' (Jansen and Nap, 2001; Rockman and Kruglyak, 2006). Brem *et al.* (2002) identified these so-called expression QTLs (eQTLs) in yeast and showed that they could map in *cis* (close to the gene whose expression they controlled) or in *trans* (distant from the gene in question). The former might include sequence polymorphisms in a gene that influence mRNA processing (e.g., in a splice donor site), stability (e.g., a nonsense mutation leading to nonsense-mediated decay), or synthesis (e.g., in a promoter). Polymorphisms in the genes that encode transcription factors (TFs) or other regulatory proteins can lead to *trans*-eQTL (the TF-encoding gene is distant from the gene whose expression is measured, **Figure 6**). *trans* eQTL are more likely to be pleiotropic, leading to altered expression levels of multiple downstream genes. A number of eQTL studies have been performed in food animal species (Steibel *et al.*, 2011), but these can be challenging, especially for outbred species with modest family sizes (Haley and de Koning, 2006; Kadarmideen *et al.*, 2006). Among the biggest challenges is accurately assessing statistical significance. For example, if a segregating population is genotyped at 50 000 SNP and the expression of 10 000 genes are measured, 500 million possible SNP-gene associations are examined, a massive multiple hypothesis testing problem. As with so many aspects of genomics, one can be confident of getting results, but it may be hard to know what those results mean.

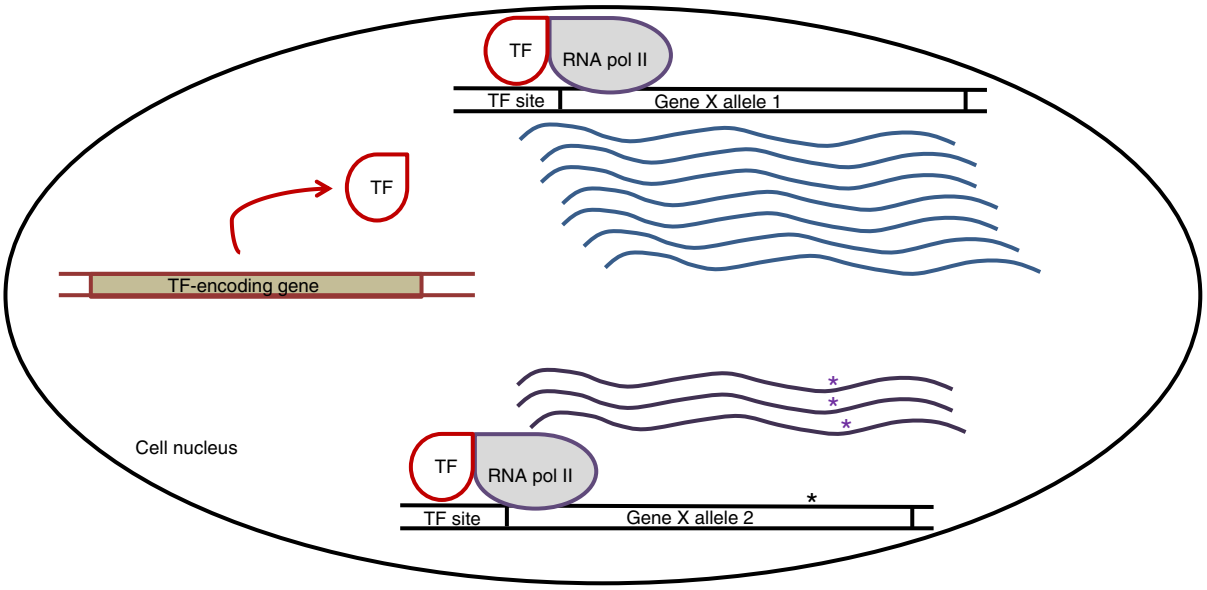

Figure 6 Expression quantitative trait loci (eQTLs) and allele-specific expression (ASE). Genetic polymorphisms that influence the level of mRNA expression of gene X (eQTL) could exist within one or both alleles of gene X itself (for example, in an enhancer, promoter, coding sequence, or UTR) in which case this would be a *cis*-eQTL, or they could exist within a regulatory gene, like the transcription factor (TF)-encoding gene shown here (only one of the two TF alleles is shown) in which case they would lead to a *trans*-eQTL (distant from gene X in the linkage map). ASE for gene X is observed when one of the two alleles expresses significantly more mRNA than the other (here allele 1 expresses more than allele 2). To observe this, there must be a polymorphism in the mRNA sequence (e.g., asterisk in allele 2). Note: this need not be the polymorphism that causes the ASE effect. The causal ASE polymorphism may be in an exon, an intron, or a flanking sequence of gene X, but it must be in *cis*, i.e., mapping in or near gene X itself, because both alleles 1 and 2 are exposed to exactly the same *trans*-acting environment.

Allele-Specific Expression

Another transcriptomic approach involves allele-specific expression (ASE) (Pastinen and Hudson, 2004; Pastinen, 2010). In ASE, the relative expression is measured of the two copies of any unique gene in a diploid cell (**Figure 6**). This requires a sequence polymorphism within the gene's mRNA that distinguishes one allele from the other (i.e., a coding SNP (cSNP)). ASE can easily be measured using reasonably deep RNA-seq data, but other, more directed approaches also are available. Because food animals are outbred, any individual's genome contains abundant cSNPs. However, F1 progeny from a designed wide cross often are examined to maximize cSNP frequency and distinguish between maternal and paternal alleles. (Generally, expression is also measured in the parents to compare with the F1, and parental genomes may be sequenced to identify the polymorphic cSNPs in advance.)

The goal of ASE is to detect sequence changes that influence the level of gene expression, but, in contrast to eQTL, ASE in the F1 is only sensitive to *cis*-acting polymorphisms. The two different alleles coexist in the same nucleus and therefore are in the same environment of *trans*-acting factors (*trans*-effects can be distinguished by comparison of the F1 allele ratios to average parental values). ASE requires neither segregating families nor linkage analysis. Although it might be expected that maternal and paternal alleles express themselves equally for most genes, and indeed this is usually the average outcome, large numbers of genes exhibit ASE in most, if not all, individuals (Pastinen and Hudson, 2004). Some of this ASE will be due to epigenetic effects such as imprinting (parental sex-specific allele programming, discussed under the Section Epigenetics below). However, sequence polymorphisms within the gene whose expression exhibits ASE are most often involved. Generally, it is not the cSNP used to detect ASE that causes the ASE effect. The former must be present within the gene's exons, whereas the latter could be anywhere in the nearby vicinity of the gene (example *cis*-acting mechanisms are given above). As with other transcriptomics, the output of ASE will be a list of gene identity numbers (associated with ASE level and, hopefully, significance values) that requires downstream analysis. One approach to narrowing that list is to specifically identify significant changes in ASE due to some treatment, for example, infection (Maceachern *et al.*, 2011). Such changes may be due to the treatment somehow differentially modifying the response of the two alleles (e.g., a virus produces a TF that binds better to one allele than the other), but it also could be a generic effect that raises a previously insignificant ASE ratio to a statistically significant difference (or vice versa).

Proteomics

Protein Expression Levels

One aspect of proteomics involves the global measurement of protein levels within a given cell or tissue type or in response to a specific treatment. This is fully analogous to transcriptomics in concept, but the task is complicated by the myriad posttranslational modifications of proteins and by the fact that

proteins occupy various cellular compartments with differing biochemical properties. Most current large proteome surveys rely on mass spectrometry (MS) (Yates *et al.*, 2009) as the primary detection tool. Typically, fractionation steps (e.g., differential centrifugation, gel electrophoresis, and column chromatography) are performed on cell extracts, along with specific proteolysis into peptide fragments that are then resolved by MS (most often tandem MS/MS, two MS runs with a further fragmentation in between). MS very accurately measures the charge/mass ratio of any peptide and therefore its amino acid composition. Tandem MS/MS results can determine peptide amino acid sequences. The main contribution of genomics to the process is that, based on the annotated reference sequence, the peptides and their mass spectra can be predicted for any protein in the genome and matched to the MS/MS output. Of course, this is complicated by posttranslational modification (as well as RNA-editing), but these factors can be taken into account, where predictable. This approach has been used to analyze the proteome of whole organs of food animals (e.g., McCarthy *et al.*, 2006) and their response to treatments (e.g., Thanthrige-Don *et al.*, 2009). Owing to variable yields during the fractionation steps, these methods sometimes do not provide good estimates of the relative amounts of the various proteins detected in the starting tissue. However, this problem can be obviated by other techniques, for example, differential heavy isotope labeling and comparing peaks of labeled to unlabeled peptide fragments (Brewis and Brennan, 2010). The eventual output of these methods will be lists of proteins with associated expression levels that can be analyzed further using clustering, GO, and pathway analysis as described in the Section Transcriptomics.

Protein–protein Interactions

The sole function of most mRNAs presumably is to template protein synthesis, whereas proteins have an enormous variety of molecular functions and cellular locations, making the domain of proteomics much broader than transcriptomics. Only one additional aspect will be discussed here, that of protein–protein interactions (PPIs). Usually this refers to physical interactions, i.e., direct contact (stable or transient) between the protein partners. However, proteins also interact functionally, for example, as part of a common pathway such that altering one of the proteins affects the function/role of the other. Several methods have been used to detect PPIs (**Table 4**). Among the most powerful is yeast two hybrid (Y2H) analysis originated by Fields and Song (1989) with a number of variations subsequently developed. Y2H provides a genetic method to detect a physical PPI (**Figure 7**). It takes advantage of the fact that most transcriptional activators exhibit a domain structure consisting of, at least, a DNA-binding (DB) domain and a transcriptional activation (TA) domain in which the two domains are encoded by non-overlapping sequences. Y2H employs recombinant DNA methods to fuse the DB domain sequence to any protein of interest (or a portion thereof), often called the bait. Likewise the TA domain is fused to another protein, the prey. The DB-bait and TA-prey hybrid constructs are transformed into a yeast strain with one or more reporter genes (selectable markers and/or color markers like *lacZ*) driven by promoters that require DB-TA transactivation to function. Only if bait and prey protein domains interact will the reporter(s) function and a PPI be scored (**Figure 7**). Rather than using a single bait or prey protein, clone libraries can be generated that contain large, even genome-wide collections of proteins, each individually fused to DB or TA. The libraries can be cross-screened to generate large 'interactomes' of PPIs for a given species (Simonis *et al.*, 2009; Venkatesan *et al.*, 2009). Protein complementation assays work similarly, except the PPI directly generates a functional reporter protein rather than a transcriptional activator that drives reporter genes.

Affinity purification/mass spectrometry (AP/MS) PPI methods are purely biochemical (Rigaut *et al.*, 1999). Recombinant proteins are generated in which a bait protein is fused with sequences (usually two in tandem) that encode binding to different affinity columns. Extracts of cells expressing the fusion are passed over the columns. All proteins (prey) bound to the affinity-purified bait are identified by MS. AP/MS requires that the PPIs in question be stable to cell lysis and passage on the columns, under whatever (mild) conditions are used. An advantage of AP/MS is that all components of multiprotein

Table 4 High throughput protein–protein interaction (PPI) methods[a]

Technology	*Brief summary*	*Advantages*	*Disadvantages*
Yeast two hybrid (Y2H)	Fusion proteins bind to transactivate reporters	High throughput, need not use full-length proteins	PPI must occur in a yeast nucleus in the correct orientation
Protein complementation assay	Fusion proteins bind to form an active reporter protein	Similar to Y2H	PPI must occur in the correct cell location in the correct orientation
Mass spectrometry of affinity-tagged complex (AP/MS)	Affinity tag purification of protein complexes followed by MS	Physiological, one bait can pull down a large complex	Interactions must be stable to purification, affinity tags could interfere with PPI
Synthetic lethality	Two mutant proteins together are lethal, but not individually	Physiological, can detect genetic versus physical PPI	Works best in model genetic species, need mutant collection
Coexpression	Proteins (or mRNAs) show common expression under multiple conditions	Fast, lots of existing data	Coexpression likely to correlate poorly with other PPI

[a]See von Merling *et al.* (2003).

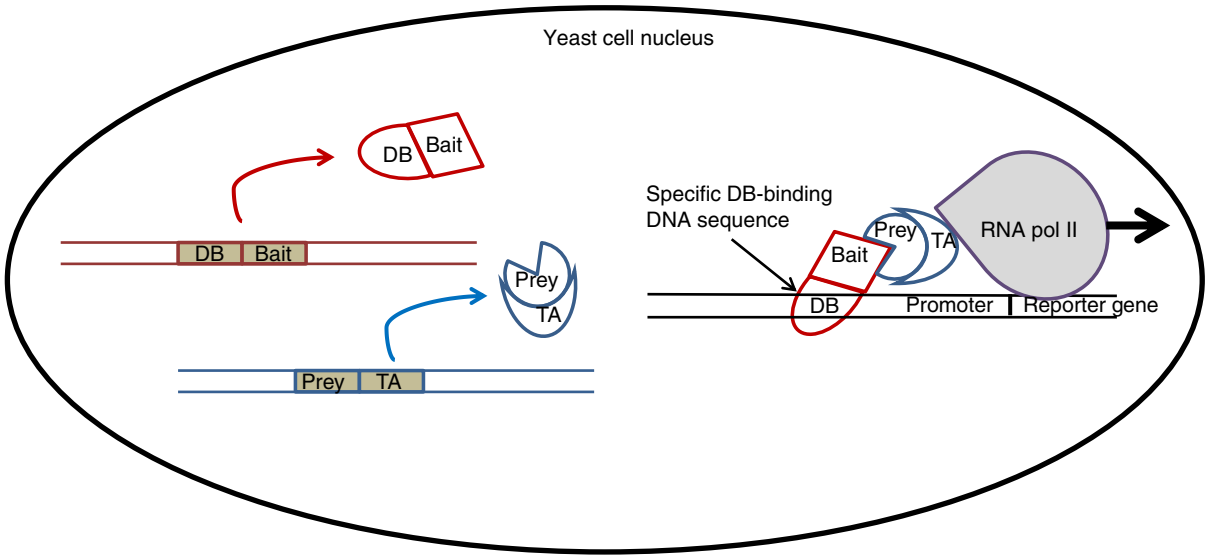

Figure 7 Yeast two hybrid (Y2H) system. Two fusion protein-encoding DNA constructs are made and introduced into the cell (left); one encodes the DNA-binding (DB) domain of a transcription factor (TF) (e.g., *GAL4*) fused to one or more 'bait' proteins of interest, whereas the other encodes the TF-transactivation domain (TA) fused to one or more 'prey' proteins. If (and, hopefully, only if) the bait and prey domains bind to one another, the two fusion or hybrid proteins couple to generate a functional complex that both binds to the specific TF DB site and transactivates RNA polymerase II. A reporter gene (right, usually multiple independent reporters are used) is constructed with the appropriate binding site such that it only functions when activated by a DB-bait–prey-TA complex.

assemblies containing the bait fusion can be identified, not just those in direct contact with the bait.

A purely genetic PPI method involves synthetic lethality (or synthetic interaction) between genes encoding two proteins. Synthetic lethality occurs when mutation of genes A and B together confers lethality (or a significant growth reduction) under a certain condition (e.g., elevated temperature), whereas mutants in A or B alone do not. Synthetic interactions do not necessarily require contact between the A and B proteins. For example, A and B might encode redundant functions (e.g., enzymes catalyzing the same reaction) or generate insignificant loss of fitness when only one is mutant, whereas mutation of both lowers fitness below a critical threshold. Synthetic lethality has been most effectively applied in model genetic organisms such as yeast (Tong *et al.*, 2001).

Venkatesan *et al.* (2009) calculated that the human interactome consists of 74 000–200 000 PPI, although this involved a number of assumptions and is likely an underestimate. All the methods mentioned have large false negative rates, and typically only a small fraction of PPIs are positive for all of multiple independent screening methods (Simonis *et al.*, 2009). Although such methods have been powerful in generating large PPI networks that can be used similarly to pathway analysis, they currently fail to fully capture organismal complexity or to provide much predictive value, at least for food animal species.

Epigenetics

Overview

Epigenetic phenomena are heritable changes that do not involve changes to the genome sequence (see Bird, 2007, and Bonasio *et al.*, 2010, for alternative definitions). Several epigenetic phenomena have been known for decades, such as position effect variegation (the same gene sequence is active in one chromosome location, but not in another) and X-inactivation (one of two equivalent X chromosomes in female mammals is almost totally inactive). Another example is that of imprinting, in which males and females specifically restrict the expression of certain genes they transmit to their offspring. Even though the imprinted gene sequence may be identical, only the paternal or only the maternal allele is expressed (regardless of sex of the offspring). The imprints on these genes are then erased and replaced with the appropriate sex-specific imprints in the offspring's germline. Imprinting probably impacts a few hundred genes that tend to be clustered in the genome of mammals and is thought to have evolved due to differing interests between male and female parents in offspring survival. (Obviously, both parents have an interest in maximizing progeny survival, but the female, especially among placental mammals, has a concurrent interest in her own survival in the face of demands on maternal resources by the fetus or newborn.) A good example is found at the insulin-like growth factor 2 locus at which an imprinting control region (ICR) is present in the genome between the *IGF2* gene and its enhancer. On the maternally derived chromosome, the ICR binds a protein (CCCTC-binding factor (CTCF)) that blocks or insulates *IGF2* from any enhancer effect. On the paternal chromosome, ICR DNA is highly methylated, CTCF does not bind, and the enhancer activates full expression of *IGF2* (Bell and Felsenfeld, 2000; Hark *et al.*, 2000). Over the past 10–20 years, it has become clear that imprinting and several other epigenetic phenomena result from an interlocking pattern of DNA methylation, altered chromatin proteins, and RNA interference.

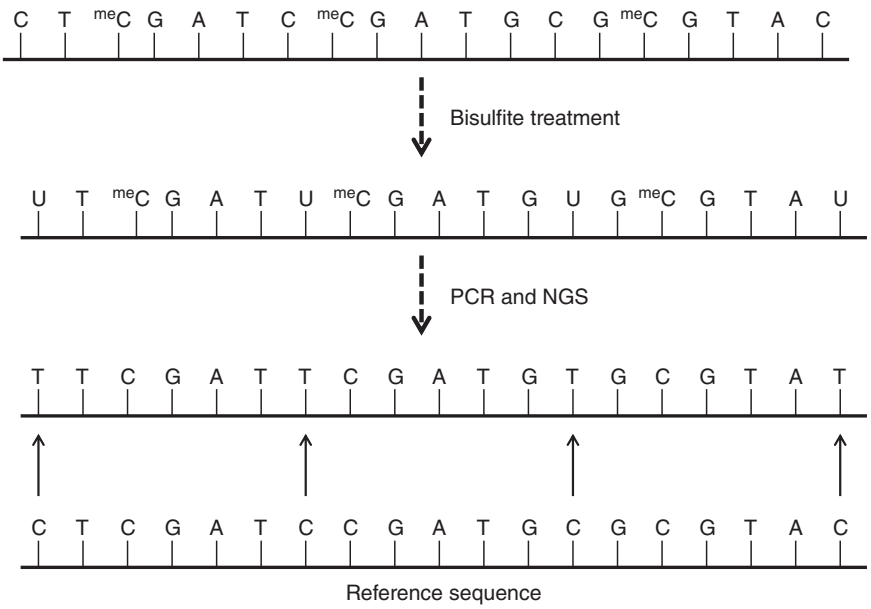

Figure 8 Methyl-sequence Genome-wide methylation analysis is done by treating DNA with bisulfite, which converts cytosine bases to uracil but has no effect on 5meC (upper dashed arrow). Subsequent polymerase chain reaction (PCR) and next generation sequencing (NGS) analysis converts sites with uracil to sites with thymine (lower dashed arrow). Comparison of the methyl-seq read with the reference sequence shows that unmethylated Cs have become Ts (upward arrows), whereas methylated C bases remain C. This will be true to the extent of the methylation (a C that originally was 50% methylated will end up 50% C and 50% T).

DNA Methylation

DNA methylation is found in most eukaryotes as 5-methyl cytosine (5meC), often at the dinucleotide sequence CpG (Zemach *et al.*, 2010). Methylation at CpG sites near individual gene promoters (often in clusters called CpG islands) has long been known to correlate inversely with nearby transcriptional activity, but recent studies provide a genome-wide perspective. The technique used (methyl-seq; **Figure 8**) involves bisulfite treatment of genomic DNA, which converts cytosine bases, but not 5meC, to uracil that subsequent PCR amplification converts to thymine in the sequence. When bisulfite-treated DNA is subjected to NGS, the extent to which a C in the reference sequence is protected from conversion to T is a measure of its methylation level. Although only limited methyl-seq studies have been done in food animals, vertebrates in general exhibit high levels of CpG methylation across the body of most genes (TSS to TTS), with a notable decrease in methylation close to the TSS, the magnitude of the decrease being correlated with gene expression level (Lister *et al.*, 2009; Zemach *et al.*, 2010). Interestingly, at least in humans, methylation at sites other than CpG (CHH or CHG, H=A, T or C) seems to be confined mostly, but not solely, to stem cells (Lister *et al.*, 2009; Varley *et al.*, 2013). Beyond these genome-wide correlations, the details of how DNA methylation regulates individual genes vary. The above example of ICR methylation activating the *IGF2* gene (simultaneously repressing the nearby *H19* gene) by blocking insulator function demonstrates one of many possible mechanisms of action. Vertebrate genomes also tend to highly methylate repetitive element sequences and heterochromatin regions (condensed blocks of chromatin often found, among other locations, in regions of tandem repeats near centromeres; Grewal and Elgin, 2007). This helps to repress transposable element activity that would otherwise be mutagenic. DNA methylation state is maintained by a system of multiple DNA methyltransferases (DNMT) and demethylases (Zemach *et al.*, 2010) and is heritable (even across generations of vertebrate animals, Natt *et al.*, 2012), in part, because after DNA replication, daughter duplexes retain methyl groups on one strand which induce maintenance DNMTs to methylate the newly synthesized strand (Bonasio *et al.*, 2010).

Chromatin and Chromatin Immunoprecipitation (ChIP)

DNA methylation does not alter gene sequence but obviously does involve covalent DNA modification. Other epigenetic chromatin marks are noncovalent. Chief among these are variations in histone proteins that make up nucleosomes (the primary protein component of chromatin), sometimes called 'the histone code' (Gardner *et al.*, 2011). Histones can be modified posttranslationally (e.g., methylation, acetylation, phosphorylation, etc.) with methylation of lysine 9 on histone H3 (H3K9) being particularly important in heterochromatin formation. Alternatively, variants can replace the common H1, H2A, H2B, H3, and H4 histones (e.g., histones H2A.Z, H3.3, and H5; Talbert and Henikoff, 2010). Other heterochromatin-specific proteins (e.g., HP1; Grewal and Elgin, 2007) bind and contribute to heterochromatin spread and maintenance. Although the association of these proteins with DNA is noncovalent, their localization can be heritable because they

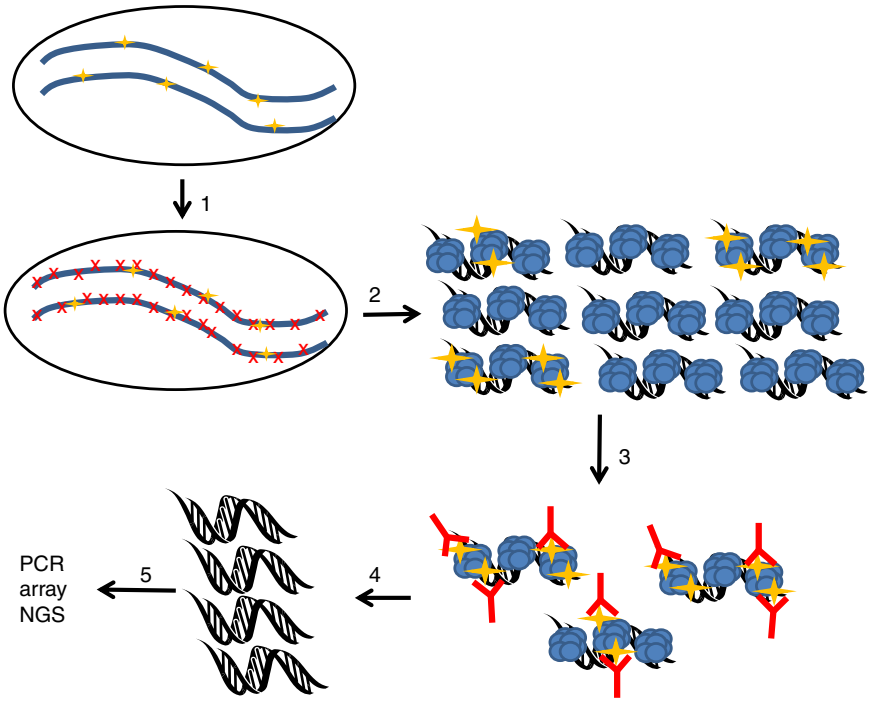

Figure 9 Chromatin immunoprecipitation (ChIP). *In vivo* chromatin (thick blue line) is shown in the cell nucleus (top left) with a localized histone modification (yellow stars), for example, H3K9 acetylation. In step 1, the cell is treated with formaldehyde to cross-link chromatin proteins to DNA (red Xs, not shown in later images). In step 2, the cell is lysed and chromatin fragmented by sonication. In step 3, a specific antibody (red) recognizing the modified histone (e.g., H3K9-OAc) is used to immunoprecipitate only those chromatin fragments containing the modification. In step 4, cross-links are reversed and the DNA is deproteinized. In step 5, enrichment of DNA fragments is assayed by gene-specific PCR, microarray (ChIP-chip), or NGS sequencing (ChIP-seq). (As a control, the same process would be done using preimmune serum or no antibody in step 3.)

remain associated with both daughter duplexes after DNA replication, and they can catalyze the local spread of the heterochromatic state (Bonasio *et al.*, 2010). Furthermore, the presence of these marks can recruit DNMTs that then proceed to methylate heterochromatin DNA. The primary method used to map these epigenetic protein marks is via ChIP (**Figure 9**). Following cross-linking of bound proteins to DNA *in vivo*, chromatin is fragmented and precipitated using an antibody recognizing the protein or modified histone of interest. Cross-linking is reversed and the enrichment of protein-bound DNA sequences is measured using PCR gene-specific assays or with microarrays (ChIP-chip) or NGS (ChIP-seq). Intensive global ChIP analyses have been performed, especially in human and model organism species (Gerstein *et al.*, 2010; The mod-ENCODE Consortium, 2010).

RNA Interference

A third major epigenetic system involves small RNAs of two types: microRNAs, miRNA, and small interfering RNAs, siRNAs, components of the endogenous RNA interference (RNAi) system. RNAi has been widely used for experimental manipulation of the expression of specific genes (Dorsett and Tuschl, 2004; Chang *et al.*, 2006), but the focus here will be on natural RNAi. miRNAs are ~23 nucleotide RNAs that function in most eukaryotic species as an internal gene regulatory network (Grimson *et al.*, 2008; Bartel, 2009). They are generated by the processing of larger initial transcripts in a multistep manner, and they function as part of a ribonucleoprotein RNA-induced silencing complex (RISC). The RISC binds to the target mRNA and can block its translation and/or degrade it to induce 'posttranscriptional gene silencing' (PTGS). miRNAs form imperfect matches to their target sequences which are found most often in mRNA 3′UTRs. miRNAs are identified by both genome annotation and deep sequencing of small RNA fractions (e.g., Burnside *et al.*, 2008). Although surveys are incomplete (lineage-specific miRNAs can be hard to distinguish by automated annotation), it is likely that most vertebrate genomes encode several hundred miRNAs. Currently, miRBase (www.mirbase.org) includes 791 mature chicken miRNAs, 360 for horse, 755 for cattle, 306 for swine, and 103 for sheep. All these are sure to be underestimates because the better annotated human and mouse genomes encode 2042 and 1281 mature miRNAs, respectively. A single miRNA can target 100 or more mRNAs, and any mRNA can contain multiple miRNA target sites. Indeed, it is clear that mRNA 3′UTR sequences have evolved to appropriately match (or avoid matching) the developmental profile of miRNA expression (Farh *et al.*, 2005). However, the effect of any single miRNA on a specific mRNA target is rarely 'all or none,' but usually modulatory in nature. Thus, miRNA and mRNA generate a complex, evolutionarily flexible, and highly redundant interlocking network of post-transcriptional gene regulation, perhaps one explanation for the only modest correlation of mRNA and protein levels discussed in the Section

Transcriptomics. Studies of the influence of miRNAs on food animal phenotypes (e.g., Trakooljul *et al.*, 2012) are still in their infancy.

The other major component of RNAi machinery involves siRNAs (Grewal and Elgin, 2007). (There are also piRNAs that seem to function during meiosis and will not be discussed further, Castel and Martienssen, 2013.) siRNAs are generated by digestion of double stranded RNA (dsRNA) by *Dicer* ribonucleases. The dsRNA can either be exogenous (e.g., dsRNA generated during the replication of RNA viruses) or endogenous (e.g., from bidirectional transcription of DNA, especially repeats). Like miRNAs, siRNAs can bind to RISCs and generate PTGS, but they also can block transcription of the target sequence (transcriptional gene silencing (TGS)). In doing so, siRNAs bind to an RNA-induced transcriptional silencing (RITS) complex that localizes to target chromatin sites in the nucleus. siRNAs also differ from miRNAs in that they generally are fully complementary (or nearly so) to their target RNAs. Thus, miRNAs work in *trans*, i.e., they target sequences different than their own, whereas siRNAs work in *cis*, targeting the same loci from which they are transcribed (and any like it). TGS works by a complex process in which the RITS localizes to the target repetitive sequence. Directly or indirectly, the RITS complex recruits H3K9 methyltransferase activity, HP1 binding, and other factors required for the assembly and spread of the heterochromatic state (Grewal and Elgin, 2007). Note that for this mechanism to function, TGS must be 'leaky,' i.e., there needs to be at least a low level of transcription of the heterochromatic repeats to generate the initiating siRNAs and provide the nascent transcripts with which they pair.

In summary, siRNAs, chromatin protein modification, and DNA methylation form a self-reinforcing regulatory system that allows eukaryotes to tolerate the pot`ential danger to the genome posed by transposable elements and repetitive sequences in general. Heterochromatic regions also perform essential structural roles such as the generation and maintenance of chromosome centromeres and telomeres in most species. Specific RNAs are also known to play key roles in other epigenetic phenomena such as imprinting and X-inactivation. Certain eukaryotes have been able to dispense with RNAi or DNA methylation (Grimson *et al.*, 2008; Zemach *et al.*, 2010), but all food animal species are likely to possess the full arsenal (e.g., Giles *et al.*, 2010), even though currently there is very little understanding of their role in agriculturally important traits.

Impact of Food Animal Genomics

Genomic technologies and the insights they provide will continue to advance at a remarkable pace. Just as it seems likely that many readers of this article will, at some point, have their own personal genomes sequenced, so will those of the core breeding stock of the relevant species, and just as human genomics has begun to impact most aspects of medical science, genomics will affect nearly all aspects of animal science. In addition to facilitating transcriptomics, proteomics, and epigenetics, as discussed above, genomics has already elucidated the causal alleles for numerous important monogenic traits (Andersson and Georges, 2004), several of which relate to coat or plumage color, with others influencing traits like muscle development and sensitivity to disease. In one case (Eriksson *et al.*, 2008), the 'yellow skin' allele was not only of commercial importance but also proved that both red and grey junglefowl contributed to the origin of the domestic chicken, resolving a long-standing controversy. Alleles that contribute to epigenetic determination of muscle mass have also been pinpointed (Van Laere *et al.*, 2003; Freking *et al.*, 2002; Smit *et al.*, 2003). Linkage mapping and association analysis are generating many more candidate causal alleles for a wide variety of polygenic QTL traits (Animal QTL database, http://www.animalgenome.org/cgi-bin/QTLdb/index). A major challenge for farm animal species is to develop cost-effective methods which can confirm the correctness of the candidate QTL alleles (as opposed to other alleles in LD with the candidate). Another major impact has been the remarkably rapid acceptance of genomic selection into commercial breeding strategies, especially for dairy cattle (Wiggans *et al.*, 2009) and, to some extent, in poultry (Wolc *et al.*, 2011). This is likely to continue, although the cost-effectiveness of genomic selection will depend on the population structure of the relevant commercial stocks as well as the traits of most interest.

If any message is to be derived from this article, it should be that the connection is extremely complex between the genome sequence and the traits sought to be maximized in the species of interest. Although genomic selection strategies ignore this connection and simply train algorithms on the assumption that a correlation exists, it seems likely that improved progress can be made with an understanding of the biological mechanisms involved. Among other things, a more detailed understanding of the genotype–phenotype connection might allow for rapid advances using genetic engineering, a technology not considered in this article. Although consumer and political resistance to genetically engineered animals remains significant, opposition to genetically modified crops seems to be weakening and may further decline as population growth increases the need for food in the face of limited natural resources. It would take a more prescient author than this one to accurately estimate all the ways through which genomics will impact the future of animal science, but it seems certain that it will.

Acknowledgments

The author thanks Andrew Jiang and Mary Delany (University of California, Davis) for FISH photographs used in **Figures 1** and **2**, Hans Cheng (USDA-ARS Avian Disease and Oncology Laboratory, East Lansing, MI) for comments on the manuscript, and the USDA National Institute for Food and Agriculture Multi-State Research Fund NRSP-8 for support.

Glossary

Allelic diversity Refers to the differences in deoxyribonucleic acid (DNA) between specific genes when they are in different individuals within the population of a species.

Homoeologous Refers to gene or chromosome regions that are genetically similar but not identical, particularly in polyploid species.

Quantitative trait loci (QTL) These are regions of the genome (Loci) that are associated with variation in phenotype (Quantitative Trait) of individuals in a genetic mapping population.

Retrotransposable elements These are elements in the genomes of many life-forms that can amplify themselves and move to different parts of the genome.

Translation The context in which this is used is to describe the process of transferring knowledge from research projects to application in industry.

Introduction and Key Concepts

The integration of biotechnology concepts and technologies are now accepted as part of an overall strategy in plant breeding that needs to consider water conservation, soil fertility, resistance of domesticated plants and animals to pests and diseases, and the production of quality grain from resilient, productive, and adapted varieties. Solutions involve innovation and improved management of resources, best practises, so that scale of effort is proportionate to need and opportunity. Complementing this is the need to capture biotechnological breakthroughs that can radically change the phenotypes of domesticated plants and animals for maximum performance in specified environments. Speedy delivery of new genotypes for planting is crucial and marker-assisted selection applications provide more informative diagnostic probes for identifying favorable combinations of alleles and genome segments in new germplasm. The multidisciplinary approaches that now characterize crop improvement enable a holistic systems approach to the study of expression and regulation of genes (and gene networks) at various levels of the plant (i.e., organism, tissue, organ, and cellular level) and developmental stages, in order to identify key cues in the plant environment, which influence the final phenotype of the plant.

Initiatives to generate reference genome sequences for rice, barley, and maize have provided the basis for an increasing number of structural/functional studies cataloging and characterizing major genes underlying important agronomic traits. Completion of the reference sequence in rice heralded the beginning of a new era (the postgenome era) in which a suit of complementary 'omics' disciplines (i.e., transcriptomics, proteomics, and metabolomics) can now exploit and leverage the knowledge of the full genome sequence to discern at greater resolution than ever before, the complex regulatory mechanisms determining expression and function. For wheat, the genome sequence representation in relation to high-resolution genetic maps is still in progress and will be based on a chromosome-by-chromosome analysis (Feuillet *et al.*, 2012).

As crop researchers transition into the 'postgenome' era, the expanded knowledge base conferred by having sequenced reference genomes will facilitate improved efficiency for delivering crop genetic gains by way of more targeted research that is better equipped to accurately identify, evaluate, and quantify: (1) the genetic potential held in crop genomes (and or subspecies/population) which is currently underutilized, in as yet uncharacterized gene(s) and/or unidentified alleles, that confer to plants the ability to thrive in rapidly changing environmental conditions caused by climate change (and the emerging biotic and abiotic stresses accompany these changes), and (2) the relative level of plasticity of particular crop genomes to evolve and thrive in response to changing environmental stresses, and the extent to which favorable heritable mutations and/or epigenetic changes may influence this adaptive evolution.

Parallel and ongoing research for the advancement of genomics platforms, sequencing technologies, and molecular marker development will continue to be essential in providing the molecular tools to capture and introgress existing and evolving allelic diversity for new cultivar development. Wide crossing and genetic transformation programs are currently the main sources of new genetic variation. In the case of an emerging threat to wheat in the form of the stem rust Ug99, for example, a basic strategy is to build a combination of genes into a new source of resistant phenotypes which may include unknown additive genes to achieve long-term resistance (Singh *et al.*, 2006). This process can be accelerated by new insight into the molecular basis for disease resistance. Similarly, increased efficiencies in photosynthesis and water use, as well as the incorporation of nutritional attributes, also require more fundamental changes to the genomes of mainstream cereals in order to provide grain for future generations. An important variable in dealing with a polyploid crop such as wheat is that it shows homoeologous gene silencing (Mochida *et al.*, 2003; Zhang *et al.*, 2008; Bottley and Koebner, 2008). Bottley and Koebner (2008) identified homoeolog nonexpression for 15 single-copy genes across a panel of 16 wheat varieties and found that for the expression profiles of eight genes only two varieties shared the same pattern of silencing. Homoeologous gene silencing can be

 doi:10.1016/B978-0-444-52512-3.00211-4

tissue specific and is most likely a significant factor in generating phenotypic variation.

Plant breeding in the postgenome sequencing era is developing capacity to utilize the very large databases of molecular markers linked to key agronomic traits. Genome wide association studies (GWAS) in rice, maize, and barley have provided high-density single nucleotide polymorphisms (SNPs) coverage of genome regions controlling components of yield. For wheat, the high-density SNP technology is also in place (**Figure 1**; Cavanagh *et al.*, 2013). The genome sequences available for cereals and the parallel functional (mutation and transformation) studies in rice and Arabidopsis have provided examples of successful 'walking' to a gene of interest. The challenge for plant genetic improvement resides in combining genetic gain and improvement in management practises for increasing yield, with the targeting of food crops to particular food products. Changing environments in soil fertility and climate need to be considered as classical G×E (genotype by environment) interactions, but in the context of changes in field and trait-management variables. Although historically improvements have been achieved through plant breeding based on crosses between parents that show attributes of interest, more recent developments have, as noted above, considered targeted introductions of genes through transformation technologies.

When crosses are made between two individuals, the genetic differences between the two individuals, which can be defined at the level of DNA sequences, will segregate among the progeny of the cross. Differences between individuals at the DNA level are called polymorphisms and can be assayed as molecular markers using a range of standard molecular technologies. The pattern of segregation of molecular markers relative to each other, among individual progeny, reflects their distribution along the long linear strand of DNA that makes up a chromosome so that molecular markers on different chromosomes will segregate at random from each other among the individual progeny from a cross. Molecular markers on the same chromosome will show nonrandom segregation from each other and this apparent linkage between the markers will depend on how far apart the molecular markers are from each other in the chromosome. When molecular markers are far apart, the meiotic process of recombination has a greater probability of separating the molecular markers than when they are very close together (=closely linked) and thus the % recombination provides a measure of genetic distance. This distance is measured in units called centiMorgans (cM). When phenotypic characteristics are determined for each of the segregating lines derived from a cross, the variation in the traits measured can be statistically associated with a polymorphism in the molecular marker (=allele) between the parents used in the cross and as these associations generally account for proportions of variation in the phenotype, these associations are referred to as quantitative trait loci (QTL).

The high-resolution genetic maps shown **Figure 1** derive from crosses between wheat lines Westonia × Kauz (far left panel) and a multiparent cross called MAGIC (middle panel, based on Cavanagh *et al.*, 2013) and were produced by assaying many SNPs using the 9000 SNP array made available by Illumina (Cavanagh *et al.*, 2013). The genetic maps for chromosome 7A are shown as an example (for a published example for chromosome 2D of wheat, see Jia *et al.*, 2013). The genetic map on the far right is a composite map and summarizes the broad output from a literature focused on mapping QTLs for phenotypes that are important in agriculture (green lines on the far right of **Figure 1**). QTLs usually occupy a region of the genetic map rather than a single point because of the variation inherent in measuring a phenotypic trait.

Molecular markers that are shared between the many crosses analyzed in the literature provide the basis for linking the maps to each other and, importantly, to link the QTL that have been mapped over an extensive period of time and in different environments, to the contemporary high-resolution molecular genetic maps. The DNA sequences of the molecular markers also provide a direct link to the reference genome sequences that are being determined and allow the location, or projection, of QTL on to the DNA sequence for analyzing the genes that underpin the QTL. The lines joining the maps indicate the shared location for a molecular marker and **Figure 1** shows a generally good alignment between the maps although the detailed alignments of some regions indicate a reversal in the order of molecular markers in one map relate to the other. These reversals in order may indicate genuine differences at the DNA level between wheat varieties due to an altered distribution of repetitive DNA sequences, or regions of the genetic map that require re-examination to check for errors. The maps illustrated are displayed using the software called CMap.

The releases of contemporary varieties now generally describe the integration of molecular markers (the outputs from genomics) into the selection technologies utilized for both the selection of parents as well as the selection of progeny from crosses to carry forward in the breeding scheme (Lee *et al.*, 2011; Miedaner and Korzun, 2012). Although the use of molecular markers provides faster results, it is critical that the linkage between the molecular marker and the trait of interest is reliable. In the postgenome sequence era the availability of molecular markers tends to be no longer limiting and this has turned the focus on improving the accuracy of assessing the phenotypes that are important for success of the breeding program (Miedaner and Korzun, 2012).

The Basic Technologies

Genome sequencing of cereals is now maturing as the bacterial artificial chromosome-based sequence assemblies for rice, maize and barley (International Barley Genome Sequencing Consortium, IBGSC, 2012) are being utilized to display phenotypic traits important to the industry on the genome DNA sequence (**Figure 1**). For hexaploid wheat (Brenchley *et al.*, 2012) and the A genome (Ling *et al.*, 2013) and D genome (Jia *et al.*, 2013) diploid genome donors, the whole genome sequencing technology has provided an important step in assigning genome sequences to molecular genetic maps and traits of agronomic significance (Feuillet *et al.*, 2012). The physical/sequence map for barley, for example, comprises 4.98 Gb with 79 379 transcript clusters identified using alignments with cDNA and RNA-seq data, and homology to genes in other plants (Middleton *et al.*, 2012). Based on RNA-seq data, at least half of the genes classified in barley show for alternative splicing (IBGSC, 2012), a process that can be a significant variable in establishing the final phenotype.

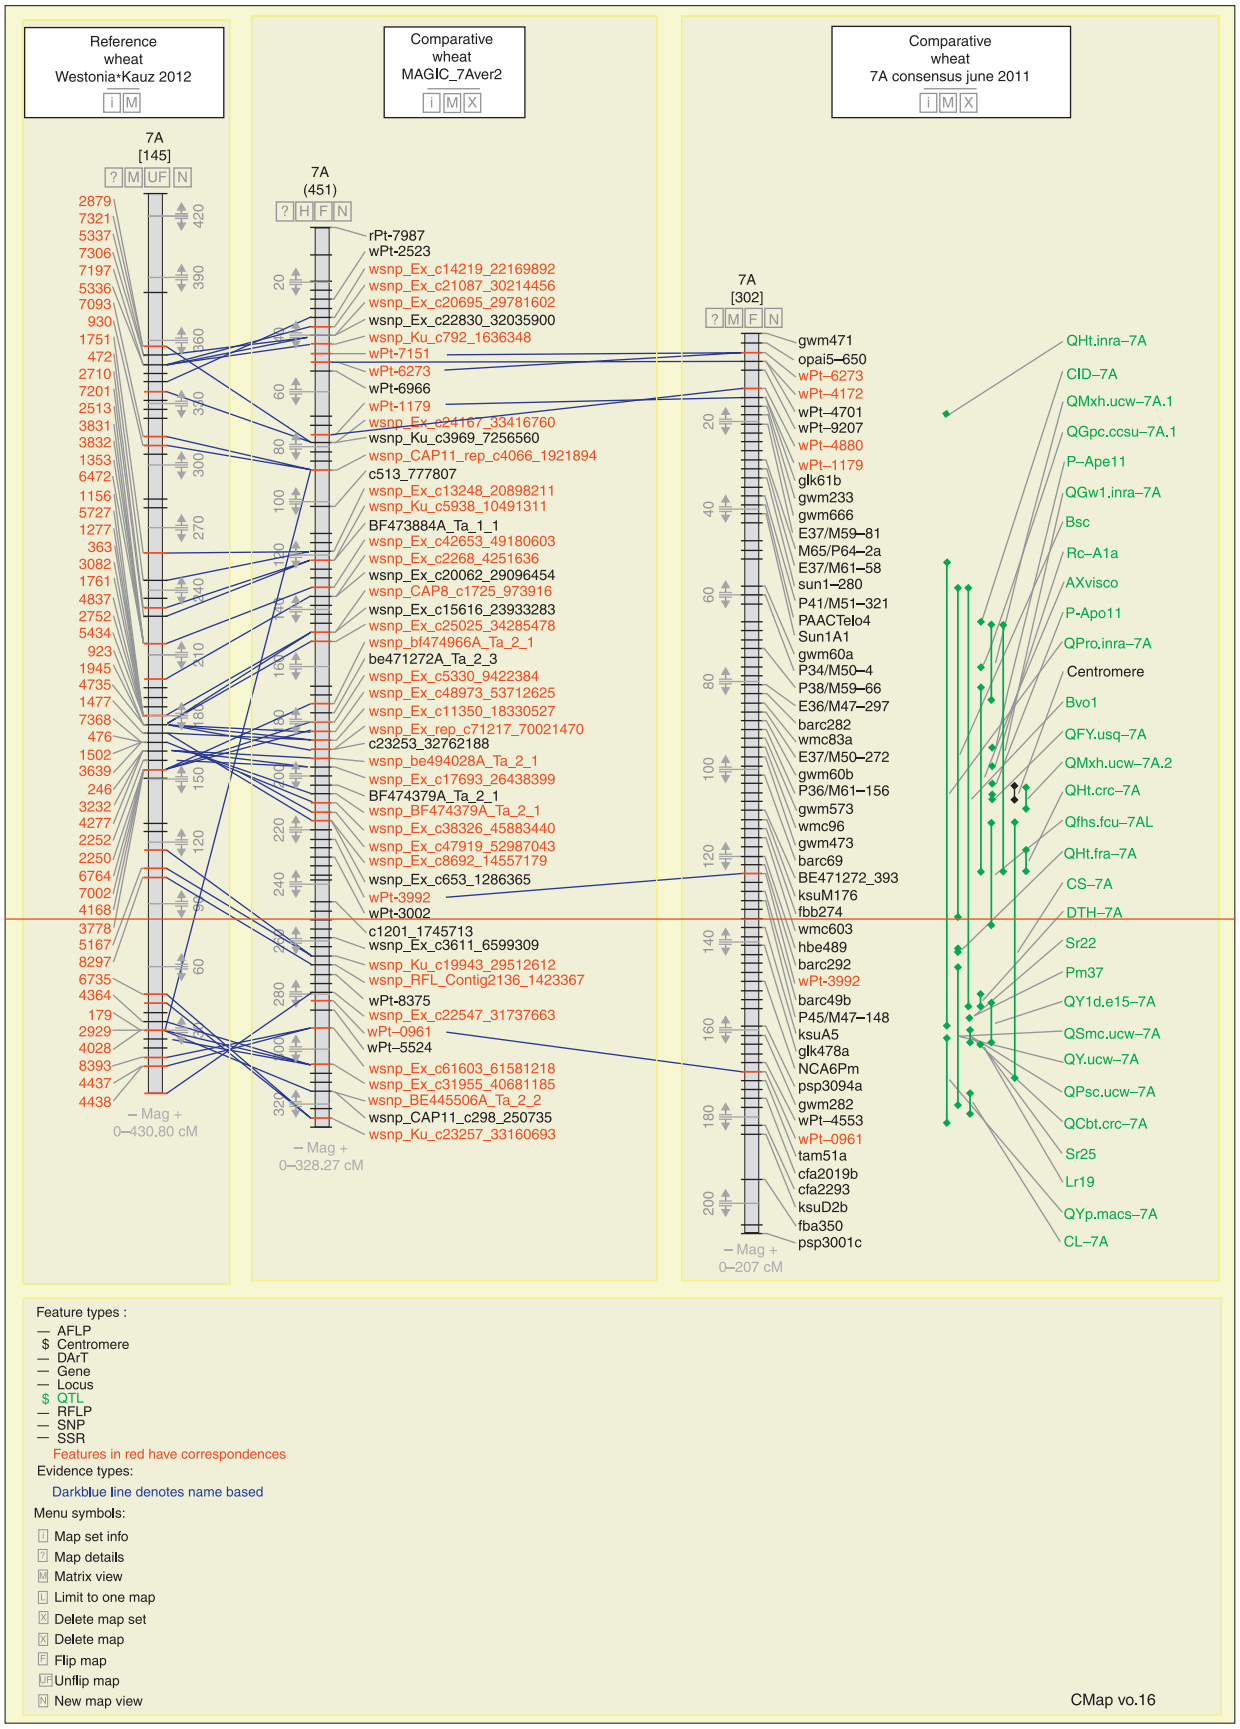

Figure 1 Comparative map of chromosome 7A.

The retrotransposable element/repetitive sequence content of cereal genomes is generally estimated to represent over 80% of the total DNA sequence. Advances in barley are representative of what is happening in the scientific area and have provided the mapping of SNPs using genome sequencing (IBGSC, 2012). Surveys of wild and cultivated barleys by comparative genome hybridization arrays (Muñoz-Amatriaín *et al.*, 2010) indicate that a significant proportion (15%) of the barley genome is affected by copy number variation (CNV) in DNA sequences. The telomeric regions of chromosomes were enriched for CNVs and this distribution correlated with an enrichment of genes in these regions and may thus contribute to the phenotypic diversity of barleys (Muñoz-Amatriaín *et al.*, 2010). These variable regions of the genome can now be assigned to the conditionally dispensable regions of the genome discussed in Appels *et al.* (2013).

The transfer of basic findings from barley genome studies into industry is based on the utilization of molecular data to predict phenotypes so that speed and efficiency is increased in breeding programs as well as reducing costs (Waugh *et al.*, 2010; Comadran *et al.*, 2011; Okagaki *et al.*, 2012; Blake *et al.*, 2012; Berger *et al.*, 2012). Tools such as The Hordeum Toolbox (THT) provide a good model for integrating extensive phenotypic and genotypic data sets for further downstream analyses (Szűcs *et al.*, 2009; Blake *et al.*, 2012; Matthews *et al.*, 2012) as well as the sharing of data between breeding programs. The analysis of a complex trait such as resistance to fusarium head blight (FHB), for example, requires the integration of a broad range of variables including the identification of resistance haplotypes in wild germplasms and QTL for FHB resistance in molecular marker genetic maps (Huang *et al.*, 2013). The studies can provide novel alleles for FHB resistance. The broad integration of technologies, particularly through the increased use of GWAS (Berger *et al.*, 2013; Cuesta-Marco *et al.*, 2010), expands the database of molecular information linked to phenotype and THT provides a valuable model for the integration of data and adoption by industry.

Rice also provides a well-developed model for the translation of genome-based research to breeding outcomes. GWAS have been carried on a very large scale in rice by Susan McCouch and colleagues (summarized in Appels *et al.*, 2012) using 413 diverse rice varieties and a 1 M oligonucleotide genotyping array, estimated to assay SNPs every 0.4–0.5 kb of genomic DNA. The study identified associations consistent with many previously reported QTLs as well as new candidate chromosome regions and genes contributing to agronomically important phenotypes (Zhao *et al.*, 2011).

Better utilization of wild relatives of rice to improve all aspects of yield in cultivated rice is a clear output from the studies to define the *Oryza* sp. genome (Kovach and McCouch, 2008). The wild relatives of rice carry sources of genes and alleles that have been lost through the domestication process to produce cultivated rice. Targeting wild relatives (based on GWAS-based identification of chromosome regions controlling agronomic traits) for crossing to cultivated rice opens the possibility for transgressive segregation to enhance specific features in rice cultivated in particular environments (Kovach and McCouch, 2008) and this is now carried out in developing new germplasm for breeding programs.

The Phenotype and Environment

A phenotype of central importance in crop breeding is yield stability, both in terms of total yield (underpinned by grain number and size) and consistency of quality attributes specific to end use and classification for processing. This is particularly important as climate change introduces conditions not previously experienced. Wheat grain yield has many components including whole plant attributes for optimal establishment and maturity/height features that in turn confer adaptive traits better enabling the plant to be suited to the environment in which it is grown. The supply of sugars to immature pollen in the developing head, and thereafter maturing grain during grain fill, has been identified as a critical plant metabolic phase determining grain yield and size, a result which has been consistently reported in studies on tomato (Ruan, 2012), cereals (Dolferus *et al.*, 2013), and tobacco/Arabidopsis (Le Roy *et al.*, 2013). Abiotic stresses (particularly water deficiency and frost) affect the developing spike and maturing grain due to the downregulation of key carbohydrate mobilization and cleavage genes (cell wall invertases and fructosyl transferases and exohydrolases). Tolerance at the genetic level requires expression of these genes under stress conditions to be maintained so that the developing pollen and grain receive sufficient energy supplies for development to reach completion unimpeded (Ruan, 2012; Barrero *et al.* 2011; Dolferus *et al.*, 2013; Moghaddam and Van den Ende, 2012).

The major genes underpinning tolerance to a number of biotic stress factors includes genes belonging to the NBS-LRR class of proteins which have conserved features relating to signal transduction involved at the host–pathogen interface. Genome-level sequencing in wheat, for example, has demonstrated that the tan spot resistance *Tsn1* gene encodes a NBS-LRR protein (Lu *et al.*, 2011) consistent with gene structures found in other resistance genes (e.g., *Rpg5* in barley, Brueggeman *et al.*, 2008). In contrast, the leaf rust *Lr34* gene (Krattinger *et al.*, 2009) has been identified as belonging to the ABC transporter class of gene, postulated to be involved in secreting a currently undefined molecule to inhibit the growth of fungal hypha penetrating the leaf tissue. The stripe rust resistance *Yr36* gene encodes a protein with a novel architecture resulting from domain reshuffling involving a kinase and a putative lipid binding domain (Fu *et al.*, 2009). The stem rust resistance *Sr2* gene in wheat has not been definitively identified but a cluster of germin-like protein coding genes is located at the *Sr2* resistance locus and these have characterized as being analogous to the germin-like cluster of genes encoding blast resistance in rice (Breen and Bellgard, 2010).

Although components of yield can be readily defined, variation in the measured phenotype remains a significant factor in breeding programs. Breeding design must be sufficiently flexible to allow changes in crossing decisions to be made when instances of negative interactions between genotypes and environments arise. Designing trials and activities in a systematic way allows optimization of information to identify the genotypic basis of phenotypic differences in germplasm and the selection of lines for use in the crosses. The process by which these activities are structured requires the identification of parents for crosses, allocation into a design, data collection, and then the analysis of data from derived progeny. The science of trial

design and the optimization of crossing/mating information is extensive (Kempton, 1982; Singh and Hinkelmann, 1998; Smith *et al.*, 2006; Williams *et al.*, 2011) and can be simulated using tools such as QU-Gene.

Important to information collection is the concept that the breeding process involves the generation of genetic variation, followed by the selection of elite germplasm, and the characterization of elite lines for desired traits. This process has the potential for errors to be transferred into consecutive stages of the breeding process. Developing trial designs such as 'chained trial design' that minimize type-II errors (false-positives and true-negatives) are becoming important considerations for breeding. The chained designs cover multiple testing of a plot (or grain sample) by incorporating within and between replication in each step tests to allow variance estimates. The statistical methods utilized are based on mixed-model restricted likelihood (REML).

With increasing amounts and complexity of information being generated from breeding operations, breeders need to collate this information into a format for decision making. Decision-making methodologies have been well researched (Dams *et al.*, 1977; Csáki, 1985; Saaty, 2005) but less often applied to plant breeding (Timmermann, 2006). The concept of a data matrix formed by taking germplasm lines and matching each line with the results for the plant breeder to interpret is widely used. Decision matrices use a weighing or prioritizing process that allows the combining of multiple results into scores to enable data reduction and easier decision making. Statistical approaches which calculate estimated breeding values (EBVs) for a trait associated with each line are designed to reduce environmental and/or extraneous factors and thus greatly enhance the decision matrix process. Diepeveen (2011) demonstrated this process for grain quality traits in a wheat breeding program.

The incorporation of marker/genomic information into the decision matrix process distorts the decision matrix because inputs of this type comprise data points that are highly correlated with each other when they are genetically closely linked to each other (see **Figure 1** and the associated box). The incorporation of correlated data structures within a multivariate REML analyses is one tool that can be applied for data reduction of genomic information and the subsequent estimation of EBVs for decision making (Kempton and Fox, 1997).

Comparative Genomics and Phenomics

A major effort to capture plant phenotype descriptions in a standardized way is being undertaken through efforts such as the Plant Ontology project in Gramene (Ni *et al.*, 2009) and Crop Ontology (Srestha *et al.*, 2012), based on the premise that essential features of traits can be identified across a wide range of species. For example, the Zadok scale is widely used to describe stages in plant development and it has been incorporated into the Biologische Bundesanstalt Bundessortenamt and Chemical industry (BBCH) scale (Meier, 2001). The BBCH scale provides the basis for describing equivalent stages in a range of cereals which can then be linked through a website such as Gramene (Ni *et al.*, 2009). A particular advantage for cross-referencing phenotypes of diverse but related species is that advances made in well-characterized species can be more easily applied to complex species such as wheat, thus facilitating meaningful comparisons.

Plant phenotypes including aspects of maturity such as earliness per se, vernalization responses (Vrn), photoperiod response (Ppd) and height phenotypes (Rht genes), efficient plant establishment based on root growth, early vigor in vegetative growth, cold tolerance in some environments, tillering and leaf expansion constitute important features of the overall plant that have been especially well characterized at the gene-level through comparative genomics and phenomics (Feuillet *et al.*, 2012). Abiotic stress tolerance in breeding is generally environment-specific and can range from being simple to complex at a genetic level. The study of boron and aluminum tolerance (Feuillet *et al.*, 2012; Delhaize *et al.*, 2012), and water stress (preceding in the Section The Phenotype and Environment) in crops such as wheat have benefited from analyses of these traits in a range of related plant species.

Barrero *et al.* (2011) provided a detailed analysis of the potential value gained from utilizing comparative genomics as a selection tool in the preliminary stages of the candidate gene identification pipeline, in which gene structure and function information accumulated on well-studied species (particularly rice) can be transferred to complex polyploid species such as wheat. Using the grain weight QTL called QTgw.ipk-7D QTL as an example, this trait mapped to the most telomeric bin (7DS4-0.61-1.00) in the physical map of wheat chromosome arm 7DS. Barrero *et al.* (2011) estimated that a total of 173 annotated wheat EST loci were located in the wheat chromosome bin 7DS4-0.61-1.00. These wheat ESTs were then assigned positions on the rice genome and those ESTs uniquely mapping to rice chromosome 6, which is the syntenic region to wheat chromosome 7DS, were identified for further analysis. This process identified 23 wheat ESTs aligned to rice chromosome 6 from position 369 919 to 25 106 896 bp. To further narrow this 25 Mbp region, Barrero *et al.* (2011) screened the rice genome for overlapping grain weight QTLs and identified a rice qrGW-6 QTL flanked by the G200 and C235 molecular markers that were located at 50.1 and 53.5 cM on the rice chromosome 6, respectively. The genetic markers overlapping this region from the Rice Genome Annotation database resulted in 11 rice genetic markers that mapped specifically to rice chromosome 6 from 6 978 639 to 9 153 520 bp. In this way it was possible for Barrero *et al.* (2011) to reduce a 25 Mbp region for analysis down to a 2.1 Mbp region, in order to search for possible grain weight candidate genes. These candidates include genes in a diverse class of E3 ubiquitin ligases involved in protein degradation. The *GW2* gene for grain weight is in this class of proteins. Also included in this region was an E2FE transcription factor which negatively regulates cell division.

Changing Agendas to Meet New Challenges and Conclusions

Future trends in plant genetic improvement will tend to focus on utilizing molecular biological techniques to consolidate pyramiding gene networks for new purposes/end-products, combined with yield gains. Although new phenotypes such as

bioethanol production from specialized pastures and biofactories for speciality products will continue to emerge, the basic concepts for tackling the new challenges will tend to follow the approaches outlined in this article. Transformation technologies have significant contributions to make in defining the functions of gene networks and providing a potential basis for new varieties when suitable government legislation/policy can be developed. The genetic engineering of crop plants to produce biofactories in controlled environments is more likely to receive increasing attention in the future for producing high-value molecules such as vaccines (Huang *et al.*, 2010; Phoolcharoen *et al.*, 2011).

The genomic resources of grain crops can now contribute to refining molecular marker development and mapping strategies for increasing the efficiency of both the breeding processes and the utilization of diverse germplasm resources. Harnessing the genetic potential of novel allelic combinations in diverse germplasm resources will require breakthroughs in disrupting linkage blocks and/or altering recombination rates along the length of the chromosome (Yousafzai *et al.*, 2010; Saintenac *et al.*, 2011; Higgins *et al.*, 2012).

The main aim of researchers in the 'postgenome era' is to exploit data from crop genome sequences, using complimentary 'omics' tools, to continue delivering genetic gains at a rate that meets increasing global demand for grain commodities and provides yield stability to withstand climate change stresses. The success in obtaining reference genome sequences for broad acre crops is providing new high throughput technologies for assaying variation in combinations of genes that was not previously possible. In particular, it is providing the basis for improved understanding of mechanisms regulating the epigenome (postreplication modification of the genome sequence and its folded structure) which holds promise for delivering crop genetic gains via strategically targeting new adaptive alleles.

Glossary

Anaerobic digestion The biochemical conversion or fermentation of organic materials, such as biomass, by mixed bacterial communities under anaerobic (without free oxygen) conditions. The process is typically used to produce a methane-containing biogas. Anaerobic digestion also occurs naturally in solid waste landfills.

Biochar Charcoal or black carbon produced by the pyrolysis or other thermochemical processing of biomass.

Biochemical conversion Conversion by biological and chemical processing, typically through microbial systems but also involving the use of enzymes or chemical pretreatment.

Biofuel A fuel product made from a biomass feedstock.

Biomass Living material. In the context of energy and materials, biomass is nonfossil material of biogenic origin.

Biomaterial A material synthesized or produced from biological resources or biomass.

Biorefinery A processing facility, similar in function to a petroleum refinery, used to refine or upgrade biomass feedstocks to higher value fuels, materials, and other products.

Gasification The thermochemical conversion of a biomass feedstock or other organic material by heating and reaction at elevated temperatures through partial oxidation using a controlled amount of oxygen, steam, or other oxidant. Gasification is used principally to produce fuel or synthesis gases containing carbon monoxide and hydrogen along with other species.

Lifecycle analysis An accounting technique used for evaluating and comparing the environmental and other impacts of a product, process, or system from the start to end of its useful life.

Pyrolysis The thermochemical heating of a biomass feedstock or other organic material in the absence of free oxygen. The process typically produces liquid, gaseous, and solid (char) products.

Thermochemical conversion Conversion by thermal and chemical processing such as by combustion, gasification, or pyrolysis.

Introduction

Technological innovations and the complex composition of biomass offer immense opportunities for new materials and products from agriculture. Many of these opportunities also come with immense challenges. Biomass can be used to produce a wide variety of biofuels to replace petroleum and natural gas, for example, but large-scale production is at present a vigorously contested global issue with many uncertainties as to net environmental, social, and economic benefits despite the promise of increased renewable energy supplies and enhanced national and global energy security. Less heavily debated is the production of new pharmaceuticals, nutritional products, specialty chemicals, and biomaterials, but these also are subject to concerns over the lifecycle implications of feedstock production and product manufacturing. Together with new tools and techniques for crop improvement, genetic modification, and biomass conversion, agriculture has the capacity to add significant new economic and development value. Agriculture, as a primary land use sector, also has the option to transform into new ways that have little to do with food or biomass production, including land conversion to support wind and solar energy deployment that may be only partially compatible with more conventional agricultural production but which may offer greater profit to the land owner. With the overall sustainability of the current agricultural system still an open question, the expansion, intensification, or redirection of agriculture toward new markets will require careful analysis and management.

Although agriculture has long provided many products in addition to food, it has the productive capacity to supply much larger quantities of industrial feedstock for other markets, in many cases in direct competition with food production. European, US, and other national or regional policies to encourage biofuel production have been heavily criticized for this reason and for their potential to increase greenhouse gas emissions rather than reducing them as intended. Increased demand for biomass, whether food crop or otherwise but especially for food crops like corn (maize) and soybeans for industrial products, is also criticized for increasing food and feed prices with particular impact on the world's poor. This food versus fuel debate is characterized by large uncertainties that lead to difficulties in the design of effective policies for the broader use of products from agriculture. As the development of agriculture has had significant global impact due to land conversion, transitions in agriculture to take advantage of new technologies and new markets for energy, chemicals, materials, and other nontraditional products require an improved understanding of global consequences and a larger systems perspective beyond what has been applied to date. The success of agricultural and industrial research in producing new conversion methods and new products from biomass has created enormous economic and environmental potential, as well as a greater imperative for better information and strategies in managing land resources and the global agricultural enterprise.

Resources and Feedstocks

Photosynthetic Pathways, Efficiencies, and Global Biomass Production

Biomass is living material, and in the context of energy and materials from agriculture and other sources, biomass is

 doi:10.1016/B978-0-444-52512-3.00156-X

interpreted to mean nonfossil material of biogenic origin. Biomass includes purpose-grown organisms and crops as industrial feedstocks, crop, and processing residues from agricultural, industrial, and commercial operations, and biogenic fractions of municipal solid wastes and wastewaters among other sources. Agriculture is increasing its production of purpose-grown crops for energy and materials including trees and shrubs, grasses and other herbaceous materials, algae, and other aquatic and terrestrial species. Primary agricultural residues include cereal straws and stovers, animal manures, orchard and vineyard prunings, forest slash from timber operations, forest stand improvement thinnings (such as small trees and brush removed to reduce wildfire intensity), and green waste from yard- and landscape maintenance. Secondary residues arise from food processing, lumber production, and other industrial operations. Black-liquor is a lignin-containing secondary residue from pulp and paper production, but is most commonly burned in recovery boilers at the mill in order to regenerate pulping chemicals and generate steam and power. Tertiary residues are associated with end-of-use materials such as wastepaper, food scraps and other biogenic fractions of municipal solid wastes, biosolids from waste water treatment, and waste fats, oils, and greases (FOG) although advances in reuse, recycling, and product recovery are expanding the perception of these as resources rather than wastes and altering their overall economic value and utility in society. Large amounts of biomass reside in waste landfills that are now being considered for materials mining to reclaim energy and product value. Distinct in arising from different economic objectives, residues and purpose-grown crops nonetheless share many similarities in composition, use, and lifecycle impacts.

The total global resource potential in biomass from agriculture and other activities has been variously estimated. The principal photosynthetic pathway produces carbohydrate biomass from carbon dioxide and water (Calvin, 1976). The process is endothermic and requires energy in the form of light (photons, ν) as well as water as a source of electrons for the overall reduction of CO_2 to carbohydrate:

$$nCO_2 + nH_2O + \nu = (CH_2O)_n + nO_2 \qquad [1]$$

where n indicates the mean polymer chain length of the carbohydrate. The photosynthetic efficiency dictates the number of photons needed per mole of carbohydrate. Anoxygenic photosynthesis also occurs that does not result in oxygen as a product and does not use water as an electron donor (see reaction [2] below) (Sato-Takabe *et al.*, 2012; Buchanan, 1992; Cohen *et al.*, 1975).

An estimated 0.02% of the 175 PW (PW = Petawatt = 10^{15} W) of incoming solar radiation to the Earth (Hubbert, 1971) is used to produce approximately 70×10^{12} kg (70 Gt (Gt = Gigaton = 10^9 metric tons = 10^{12} kg)) of biomass each year through oxygenic photosynthesis (based on an average dry matter heating value of approximately 16 MJ kg^{-1}) (Jenkins *et al.*, 1998). More detailed analyses of biomass production by type of ecosystem yield global estimates in the range of 170–220 Gt year^{-1} (Klass, 1998; Hall *et al.*, 1993). Total plant biomass currently accumulated in all global ecosystems is estimated at approximately 10^{15} kg (1000 Gt) dry matter, or approximately 10 times annual production (Hall *et al.*, 1993; Salisbury and Ross, 1992).

Biomass is also produced through processes other than oxygenic photosynthesis. Hyperthermophilic bacteria, such as those associated with hydrothermal vents at the deep ocean floor, use chemosynthetic pathways for energy and biomass production and are utilized in symbiotic relationships by other organisms (e.g., tube worms) for survival in these extreme environments (Kato *et al.*, 2010). Overall, sulfide chemosynthesis produces elemental sulfur and water in converting carbon dioxide and hydrogen sulfide:

$$nCO_2 + 2nH_2S = (CH_2O)_n + nH_2O + 2nS \qquad [2]$$

Oxygen gas is not released by this mechanism. Sulfur metabolizing bacteria that utilize chemosynthetic pathways are now being investigated for their use in hydrogen sulfide removal from biogas produced during anaerobic digestion of manure and other feedstocks (Ho *et al.*, 2013; Camarillo *et al.*, 2013). Sulfur removal is required for the successful application of most postcombustion catalysts for NO_x emission reductions from engines burning biogas for power generation (Camarillo *et al.*, 2013; Liu and Gao, 2011).

Biomass provides approximately 15% of world energy needs, but in developing countries constitutes a much higher fraction of energy supply: 35% overall, and in excess of 80% in many rural areas (Hall *et al.*, 1993; Bain *et al.*, 1998). Globally, agriculture produces approximately 5 Gt year^{-1} of crop residues of which perhaps less than half may be sustainably available for energy and industrial purposes although larger fractions may be used in developing countries (Jenkins, 1995). Resource-focused studies of global bioenergy potentials range widely, differing by at least an order of magnitude depending on the assumptions made regarding land availability and crop yields (Berndes *et al.*, 2003). Considerations of lifecycle environmental effects, particularly greenhouse gas emissions, also influence global potentials (Searchinger *et al.*, 2008; Fargione *et al.*, 2008).

Plants utilize three principal pathways in assimilating atmospheric carbon dioxide and synthesizing carbohydrate structures and other compounds through photosynthesis. The biological or dry matter yield is dependent in part on the pathway used. Light energy is absorbed in two pigment systems called photosystem I (PS-I) and photosystem II (PS-II). In both the systems, absorption of light by chlorophyll and accessory pigments leads to the emission and transport of electrons against an adverse voltage gradient. As noted above (refer to reaction [1]), in oxygenic photosynthesis the electrons are derived from the photolysis of water mediated by a manganese-containing enzyme in PS-II (Salisbury and Ross, 1992; Marschner, 1986). Electrons are transferred from PS-II through what is called the Z-scheme to PS-I, storing energy in the carriers adenosine triphosphate (ATP) and the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) for later use in CO_2 reduction and carbohydrate synthesis. Mineral nutrients are directly involved in electron transport, and in other processes of the plant. The mineral or ash concentration and composition are often quite important in the subsequent use of the biomass, and can influence the design of the production and utilization system.

The light reactions store energy in NADPH and ATP. In the so-called C3 plants, CO_2 and water react with ribulose-1,5-diphosphate to produce 3-phosphoglyceric acid as part of the Calvin–Benson cycle. The glyceric acid is subsequently converted using NADPH and ATP into 3-phosphoglyceraldehyde and then into hexose phosphate and ribulose-5-phosphate. The latter reacts with ATP to regenerate ribulose-1,5-diphosphate, whereas hexose is used in the synthesis of the primary storage products, sucrose and starch. The C3 pathway takes its name from the 3-carbon intermediates produced during the cycle. C3 plants include the cereals barley, oats, rice, and wheat, alfalfa (lucerne), cotton, *Eucalyptus*, sunflower, soybeans, sugar beets, potatoes, tobacco, *Chlorella*, and others. Gymnosperms (with a few possible exceptions), bryophytes, and algae are C3 organisms, as are most trees and shrubs.

Along the C4 pathway, CO_2 combines with phosphoenolpyruvate (PEP) via a PEP-carboxylase catalyzed reaction to form oxaloacetate, which is reduced to malic-acid (malate) or aspartic-acid (aspartate), 4-carbon intermediates giving the pathway its name. These are translocated from the mesophyll cells where the primary CO_2 fixation occurs to the bundle sheath cells from which CO_2 is released for subsequent fixation through reactions of the Calvin–Benson cycle as in C3 plants. Decarboxylation of the acids regenerates PEP. C4 plants are usually of tropical origin and have higher photosynthesis rates and higher biological yields (dry matter production) compared with C3 plants. C4 plants include sugarcane, sorghum, maize, and Bermuda grass. *Euphorbia* species considered for direct hydrocarbon production are mostly C3, but a few have evolved to use the C4 pathway.

The third primary pathway is that of crassulacean acid metabolism (CAM) used by many succulents. The CAM pathway also fixes CO_2 via PEP carboxylase, but in the CAM species the stomata are open at night rather than during the day in order to reduce water loss. Malate is stored in the vacuoles during the night and then released during the day when the stomata are closed. CAM plants have lower growth rates than the C4 species but have high water use efficiency due to their adaptation to low-water environments, including semiarid and saltmarsh regions, and epiphytic sites, such as those used by orchids.

For photosynthetic organisms, biological yield (total biomass) is a function of the net production by photosynthesis and consumption by respiration, the latter including photorespiration in C3 plants. Respiration provides energy through the oxidation of organic compounds in generating substrates for the synthesis of other plant products in essentially the reverse of reaction [1] above. Maximum theoretical photosynthetic efficiencies can be derived based on a minimum requirement of eight photons of photosynthetically active radiation (PAR, light of 400–700 nm wavelength) per molecule of CO_2 used to produce glucose, the minimum ν in reaction [1] (Klass, 1998; Hall *et al.*, 1993; Loomis and Williams, 1963). Approximately 43% of the energy in sunlight at the ground level is contained within the PAR band, and of this a maximum of approximately 80% is actively absorbed during photosynthesis. Only approximately 28% of this energy is stored in glucose. In C4 plants respiration consumes somewhere between 25% and 40% of the energy in glucose. The maximum net efficiency of photosynthesis based on incident sunlight is therefore 6–7%. Photorespiration in C3 plants generally leads to efficiencies of approximately 3%, lower than the C4 plants. Photosynthetic efficiencies can be translated to biomass yields using site-specific insolation data and the energy content of the biomass (heating value). At maximum efficiency, theoretical yields can exceed 400 metric tons of dry matter per hectare per year. Agricultural yields are generally far below this due to nonoptimal crop conditions, limited inputs, and losses to diseases and pests. In practice, yields are also lower because not all biomass is or can be harvested. Genetic modifications and other crop improvements are widely investigated to increase productivity and yields.

Efficiencies for agricultural crops typically are of the order of 1%, although tropical crops, such as sugarcane and high-yielding grasses, can produce at 2–3% efficiency with dry matter yields of 50–100 Mg ha^{-1} $year^{-1}$. Intensive production of green algae can approach 5% efficiency, similar to the best efficiencies with C4 crops under research conditions. A maize (corn) crop grown in Davis, California achieved 5.6% photosynthetic efficiency under optimized conditions where only light was limiting (Loomis and Williams, 1963). Seasonal efficiency for many C3 crops when given sufficient water and nutrients is closer to 2% (Monteith, 1977). Natural forest efficiencies trend lower. The production of purpose-grown industrial and energy crops seeks to produce biomass at relatively high photosynthetic efficiency. Owing to the costs of inputs, an optimal production system based on maximum profit may not operate at maximum yield; however, yields are nevertheless of high relative importance to the overall economic feasibility.

Biomass can be used for remediation of environmental contamination (phytoremediation), and the use of biomass as fuel in the substitution of fossil resources can help mitigate greenhouse gas and global climate change impacts, but its production and use requires careful lifecycle assessment to ensure net environmental benefits. As noted earlier in the Section Introduction, many policies and incentives for the production of biofuels are highly controversial.

Biomass production has significant utility in serving to store solar energy. Hybrid renewable energy systems using biomass can take advantage of this attribute in helping to stabilize electricity grids supplied with high levels of intermittent solar and wind power generation.

Biomass is a distributed resource, and its use to supply large quantities of energy and materials requires relatively large amounts of land. The overall conversion efficiency from solar energy to final energy product is low due to the inherently low efficiency of photosynthesis. The overall electrical efficiency, for example, using biomass produced at 2% photosynthetic efficiency as feedstock for power plants operating at 25% average thermal efficiency is 0.5%. Solar photovoltaic systems, including inversion of DC to AC power for grid interconnection, currently generate at efficiencies of 6–12% (with peak research efficiencies well above this), but suffer from the intermittency of sunlight. The higher efficiency of direct solar energy conversion coupled with declining manufacturing costs generates competition between the agricultural and energy sectors for land resources, a subject of additional controversy and developing policy.

Improvements in biomass-fueled power systems will increase conversion efficiencies, but the overall solar conversion efficiencies for biomass are likely to remain below 1% for power. To meet the current (2013–14) world primary energy demands of approximately 600 EJ (EIA, 2013a) would require approximately 600 million hectares of land (1 TJ of energy in biomass per hectare per year) for crops continuously producing at 2% photosynthetic efficiency (approximately 6 kg per square meter or 60 Mg ha^{-1} $year^{-1}$ dry matter). This is approximately 40% of the world's cultivated land area, and 15% of forest lands. It is only approximately 30% of the area of degraded tropical lands, and half the area of these lands considered suitable for reforestation (Hall *et al.*, 1993). Abandoned agricultural land is estimated to range globally from 385 to 470 million hectares (Campbell *et al.*, 2008). The actual land requirement to meet the world energy demand would be much greater than this because of the differences in conversion efficiencies between the current energy resources and biomass to satisfy the same end uses, and because not all land would be kept in continuous production and the overall photosynthetic efficiency would not likely reach 2%. This estimate does not include aquatic or marine species such as algae that might also contribute. More considered estimates of the contributions from bioenergy range from 50 to 240 EJ $year^{-1}$ and closer to 10% of the global energy demand (Berndes *et al.*, 2003). Meeting the world energy demand from biomass is neither necessary nor desirable, but the potential scale for industrial feedstock production is large, even for relatively small shares of the energy market alone and highly significant in terms of land use impacts, both direct and indirect.

Types of Biomass

Agricultural residues

Agricultural residues are coproducts of the principal commodity production system. These include primary vegetation as well as animal manures composed of digested feeds. Corn stover, for example, which is a residue of grain production, is now receiving considerable attention as an energy resource in addition to its potential use in new materials. Increasing economic value of residue biomass can lead to changes in the overall crop production system, such as attention to improving yields of residues as well as the primary crop. Increased fertilization may be needed to replace nutrients exported with the residue biomass when harvested. Alternatively, the farming system may adapt to the application of recycled ash or other nutrients returned from the biomass utilization system. Changes in residue management can also lead to addition or loss of soil carbon, adjustment of fertilizer composition to reduce the uptake of chlorides and other constituents that can be detrimental to downstream conversion, modified tillage strategies to protect against soil erosion when residue cover is reduced or to take advantage of decreased amounts of residue needing to be incorporated into the soil, changes in irrigation practices to manage soil and crop moisture for biomass harvesting, modified chemical applications due to changes in weed, pest, and disease pressure from residue removal, and changes in the harvesting system design and operation to integrate primary crop and residue collection.

Controversy over indirect land-use change effects and food versus fuel impacts associated with purpose-grown crops for biofuels shifted focus onto agricultural residues as seemingly benign sources of feedstock. However, residue use also needs to be carefully evaluated for more global sustainability effects. Harvesting of corn stover in the midwestern US for biofuels, for example, may result in losses of soil carbon that increase the net greenhouse gas emissions above the levels for petroleum-based fuels (Murphy, 2013). Purpose-grown crops such as mixtures of native grassland perennials may prove superior in overall environmental performance (Tilman *et al.*, 2006; Murphy, 2013). Broad generalizations relating to the relative impacts of agricultural residues and industrial crops should be carefully inspected.

Other changes to the production system may occur when modifications are desired in the properties of the biomass. One example is the delayed harvesting of cereal straws to take advantage of natural precipitation in the leaching of alkali metals and chlorine to improve the combustion or gasification properties for biomass power generation and to reduce the export of nutrients from the field when harvesting residues. Residue harvesting reduces air pollution when substituted for traditional open burning disposal practices with some crops, and also removes nonvolatile nutrients such as phosphorous (P) and potassium (K) (Jenkins *et al.*, 1992). Leaching by precipitation readily removes soluble potassium and a number of other constituents and returns them to the field before harvesting, although in-field decomposition of the residue and dry matter loss may reduce the overall economic value (Bakker and Jenkins, 2003).

Residue yields from selected crops are listed in **Table 1**. The estimated production rates for animal manures are also shown. When not measured directly, residue yields are frequently estimated from primary crop yields using the harvest index, the ratio of crop yield to total above ground biomass, typically determined from test plots (Huehn, 1993). Harvested yields are typically lower than listed due to losses in collection and handling, adding to the uncertainty associated with resource supply.

Forest residues and stand improvement biomass

Forest residues include tree tops and branches from timber harvesting operations referred to as forest slash (due to the practice of removing them from the commercially valuable bole of the tree). Biomass can also be collected in the form of forest thinnings of two forms: (1) lower quality stock that is often unsuitable for traditional markets and which contributes to poor forest health or (2) as increased production from more intensively managed regrowth forests. In many temperate forests, the mean annual growth far exceeds the mean annual harvest, and the overall stand quality can be diminished. Understory brush and dense stands of trees can contribute to high fuel loadings in forests with increased danger of catastrophic wildfire, higher incidence of crown fires and greater damage and mortality among mature trees, and high costs of fire suppression if practiced. Many forests of the western United States are now particularly at risk of catastrophic fire due to high fuel loads resulting from more than a century of fire suppression (Jenkins, 2005).

Table 1 Agricultural residue yields and manure production rates

Crop residue	*Yield (Mg ha^{-1} year^{-1})*
Almonds	2.2
Apples	3.7
Apricots	3.4
Artichokes	3.8
Asparagus	4.9
Avocados	2.5
Barley	2.5
Beans	1.9
Cherries	0.7
Citrus	1.7
Corn (maize)	9.0
Cotton	2.9
Cucumbers	3.8
Dates	1.7
Figs	3.7
Grapes	3.4
Lettuce	2.2
Melon/squash	2.7
Oats	2.3
Peaches	3.4
Pears	3.8
Plums	2.5
Potatoes	2.7
Prunes	1.7
Rice	6.7
Safflower	1.9
Sorghum (grain and milo)	5.0
Sugar beets	4.6
Tomatoes	2.9
Walnuts	1.7
Wheat	3.7

Livestock manures	*Production (kg dry matter per animal per day)*
Beef cattle	4.1
Dairy cattle	5.9
Chickens (layers)	0.04
Chickens (broilers)	0.02
Turkeys	0.1
Swine	0.5

Industrial and energy crops

Terrestrial (land-based) purpose-grown industrial and energy crops are typically classified as woody or herbaceous although not all industrial crop types are readily classified in this way. Jatropha, for example, includes approximately 170 species of succulent plants, shrubs, and trees. The more common species of this plant considered for biofuel purposes is the drought-resistant shrub *Jatropha curcas* that produces an oil-bearing seed useful for biodiesel production among other uses. The plant also contains toxic compounds including phorbol esters and other terpenoid compounds, but even these also have some beneficial uses (Devappa *et al.*, 2011; Wang *et al.*, 2013a). The phorbol esters demonstrate insect deterrent and cytotoxic antitumor and antimicrobial properties (Devappa *et al.*, 2011). Woody crops are predominantly plantation trees, frequently grown in short-rotation intervals of from 1 to 20 years between harvests. Cultural practices for these crops have been well established for roundwood and papermaking, and have been more recently extended to the production of fuel wood. Herbaceous crops include annual and perennial grasses and other nonwood plants. Production practices for these crops are in most cases similar to other agricultural crops, although in both woody and herbaceous crop production, the end use for the biomass can influence the management and cultural inputs and practices employed to optimize the production system. A number of more commonly considered industrial and energy crops are listed in **Table 2** but many more have been investigated for specific material recovery or energy purposes.

Just as they are for current agriculture, water availability and water costs are key constraints in industrial biomass production. Water requirements vary considerably but are typically in the range of 300–1000 kg per kg of dry matter produced. Arid or semiarid regions of the world are not anticipated to produce substantial quantities of biomass for energy markets even where water is commonly imported for agriculture. The exception may be in the production of algae due to the high availability of solar radiation and the potential for the use of brackishwater, waste water, or seawater (Renuka *et al.*, 2013). Lands in these areas might be used in the production of feedstocks for higher value industrial and consumer products.

Biomass production can play an integral role in managing salts and remediating other undesirable impacts of irrigated agriculture in arid or semiarid regions and in reclaiming lands degraded by unsustainable agricultural practices. Integrated farm drainage management (IFDM) systems have been evaluated in California and other irrigated agricultural regions to reclaim salt-affected soils and to reduce the environmental impacts of agriculture in these areas (Lin *et al.*, 2002). IFDM systems employ sequential reuse of water through a cascade of increasingly salt-tolerant crops with the objective of continuously reducing water volume and increasing salt concentration for ultimate recovery or removal. Fresh irrigation water applied to high-value vegetable crops, for example, results in drainage water that can be applied to more salt-tolerant agricultural crops such as cotton or barley. Biomass crops, such as *Eucalyptus* or Jose tall wheat grass (*Agropyron elongatum*) are suitable for irrigation with the secondary drainage water from these, with tertiary drainage from the biomass crops applied to halophytes, and solar evaporators or other salt separation and purification systems used for final treatment and salt removal. The biomass crops transpire large amounts of water and act as biopumps to lower groundwater tables and reduce salt accumulation in the root zone, and also help in removing toxic elements, such as selenium, that is taken up and accumulated in the plant biomass. Crop harvesting removes undesirable materials from the field for downstream recovery, utilization, or disposal. Biomass yields under these conditions are substantially less than the best yields obtained for the same species under optimal conditions. Where other agronomic or environmental purposes are involved, yield is not necessarily the primary consideration for these systems although still an important consideration for economic performance. Biomass crops can in

Table 2 Selected industrial and energy feedstock crops

Woody species – biomass/fiber/pulp
Alder (*Alnus* spp.)
Australian pine (*Casuarina*)
Birch (*Onopordum nervosum*)
Black locust (*Robinia pseudoacacia*)
Eucalyptus (*Eucalyptus* spp.)
Lucaena (*Lucaena leucocephala*)
Poplar (*Populus* spp.)
Willow (*Salix* spp.)

Herbaceous species – biomass/fiber/energy grain
Alfalfa (*Medicago sativa*)
Corn/Maize (*Zea mays*)
Flax (*Linum usitatissimum*)
Hemp (*Cannabis sativa*)
Jose tall wheatgrass (*Agropyrum elongata*)
Kenaf (*Hibiscus cannabinus*)
Miscanthus (*Miscanthus* spp.)
Napier grass/Bana grass (*Pennisetum purpureum*)
Spanish thistle or Cardoon (*Cynara cardunculus*)
Spring barley (*Hordeum vulgare*)
Switchgrass (*Panicum virgatum* L.)
Triticale (*Triticosecale*)
Winter rye (*Secale cereale*)
Winter wheat (*Triticum aestivum*)

Herbaceous species – sugar/starch/biomass
Buffalo gourd (*Curcurbita foetidissima*)
Cassava (*Manihot esculenta*)
Jerusalem artichoke (*Helianthus tuberosus*)
Sugar/energy cane (*Saccharum* spp.)
Sugar/fodder beet (*Beta vulgaris*)
Sweet sorghum (*Sorghum bicolor*)

Wetland species – biomass/fiber
Cattail (*Typha* sp.)
Cordgrass (*Spartina* spp.)
Giant reed (*Arundo* spp.)
Giant reed (*Phragmites* spp.)
Reed canary grass (*Phalaris arundinacea*)

Seed/oilseed/terpenes
Amaranth (*Amaranthus* spp.)
Castor (*Ricinus communis*)
Crambe (*Crambe abyssinica*)
Euphorbia (*Euphorbia* spp.)
Jojoba (*Simmondsia chinensis*)
Linseed (*Linum usitatissimum*)
Oilseed rape (*Brassica* spp.)
Safflower (*Carthamus tinctorius*)
Soybean (*Glycine max*)
Sunflower (*Helianthus annuus* L.)
Jatropha (*Jatropha curcas*)

Aquatic species – biomass/lipids
Brown algae (*Sargassum* spp.)
Giant kelp (*Macrocystis pyrifera*)
Microalgae (*Botryoccus braunii*)
Red algae (*Gracilaria tikvahiae*)
Unicellular algae (*Chlorella and Scenedesmus*)
Water hyacinth (*Eichhornia crassipes*)

general be used for the restoration of abandoned or degraded agricultural lands (Campbell *et al.*, 2008), and economic and environmental reasons are frequently proposed for planting in marginal areas.

Short-rotation woody crops grown for energy or other purposes are typically grown in plantations with stand densities ranging up to 10 000 trees per hectare depending on the size of the tree desired at harvest, harvesting technique employed, and end use intended for the biomass (Smith *et al.*, 1997). More than 100 million hectares are in industrial tree plantations (Hall *et al.*, 1993), most in longer rotations for roundwood and pulp production. Production site selection depends on soil properties, water availability, slope, climate, and distance from market. As with agricultural crops, high yields are associated with better soil types, although trees can generally take advantage of higher groundwater tables (Siren *et al.*, 1987). Soil preparation commonly involves land clearing to remove the existing vegetation and eliminate weeds, soil amelioration to adjust pH and improve tilth, drainage, and nutrient concentrations, and leveling and in some cases mulching. The plant bed is prepared in a manner similar to agricultural crops, although tillage is typically deeper than for cereals. Following soil preparation, cuttings, slips, or seedlings are planted either manually or by machine or by machine-assist to manual planting (Golob, 1987). Soil moisture management following planting is critical as deeper tillage increases drying rates, potentially leading to inadequate water availability without rain or irrigation. Cultivation, chemical application, or mulching (including plastic sheet mulching) to control weeds, and in some cases pruning to improve shoot vigor, are typically required following planting for proper stand establishment. Some crop species, such as *Salix* (willow), are highly susceptible to common herbicides. Biological weed control is sometimes practiced, usually by planting weed-competitive crops such as *Trifolium*, although these can also compete for nutrients and water with the primary crop until good canopy cover is achieved. Fencing to control grazing by animals may also be needed. Irrigation and fertilization can be accomplished in the same manner as for agricultural crops. Drip irrigation systems can be combined with chemigation (injection of nutrients and other chemicals into the irrigation system for distribution to the plants). Frost protection is not commonly practiced, but frost damage is a concern in many locales. Where frosts are frequent, more tolerant species or varieties are selected. Fire suppression may be needed in dry areas, and varietal or species selection is important in reducing damage from insects and diseases. Plantation design can include set-aside areas harboring native predators of pests, and division of the plantation into blocks of different clones or species to make the overall plantation less susceptible. Owing to the lower frequency of planting and other operations in tree plantations, soil erosion rates are generally lower compared

with agricultural crops. Seedling survival rates in well-managed plantations are typically approximately 85%. Coppice (resprouting) crops are harvested in 3–10 year cycles, with up to six cycles before replanting. Mean annual dry matter increments in practice are 10–20 Mg ha^{-1} $year^{-1}$, generally declining at higher latitudes for reasons of climate and insolation. Crop improvements may extend these yields to 15–30 Mg ha^{-1} $year^{-1}$ or higher.

Production of herbaceous crops in many respects bears greater resemblance to conventional forage and other agricultural crops, although many of the same considerations apply to the production system design as do for short-rotation woody crops (Smith *et al.*, 1997; Gosse, 1996). Regional mixed cultivation of perennial and annual species, as opposed to large-scale monoculture, is seen in many cases to be of benefit both in terms of environmental and economic performance (Tilman *et al.*, 2006). Depending on the location, the regional mix might include legumes and warm and cool season grasses. Total dry matter yields for herbaceous species under good management are typically in the range of 10–30 Mg ha^{-1} $year^{-1}$. Sugarcane, a C4 species, is one of the most productive crops, with world average yields of approximately 35 Mg ha^{-1} $year^{-1}$ (Hall *et al.*, 1993) with fresh wet-weight yields including sugar above 250 Mg ha^{-1} $year^{-1}$ although few countries exceed 100 Mg ha^{-1} $year^{-1}$ fresh-weight (Duke, 1983). Where proposed as energy or industrial crops, particular attention must be given to the composition of the plant. Herbaceous species, especially grasses, generally contain more ash than woody species, and the ash is higher in alkali metals and silica. The latter, for example, combine at high temperatures in thermochemical systems to form slags and deposits that increase maintenance costs. Leaching with water can remove most of the alkali, and delayed harvest to take advantage of rain-washing can improve the combustion properties in the same manner as noted earlier for residues (Jenkins *et al.*, 1998; Huisman, 1999). Chlorine, primarily supplied in potassium fertilizer (e.g., as muriate of potash or KCl) or present as chloride in irrigation water, facilitates alkali volatilization and fouling at high temperatures, accelerates corrosion of metals, and contributes to acid gas (principally HCl) and toxic emissions such as dioxins and furans from combustion systems (Jenkins *et al.*, 2011). Sulfur, although typically present in plant biomass at low concentrations, also contributes to fouling and air pollutant emissions. Restricting chlorine from fertilizers in energy crop production is generally advantageous, as is proper management of sulfur. These concerns are reduced for crops grown as feedstock for direct chemical extraction, fermentation, or manufactured fiber products, where oil, sugar, starch, or structural carbohydrates are of more importance, unless ligneous residues of the fermentation are to be burned as fuel as is commonly considered for cellulosic biorefineries. However, in all cases the composition of the feedstock needs to be considered in terms of the requirements of the manufacturing or conversion process and any accompanying waste disposal. Consideration also needs to be given to the introduction of exotic species that may grow well initially but lack biological disease and pest controls in new environments and are, therefore, more susceptible to later damage or that may prove adaptive and invasive to the detriment of native species or other crops.

Except for phytoplankton, aquatic species tend to demonstrate higher yields than terrestrial crops (Klass, 1998). Aquatic species include both unicellular (e.g., *Chlorella*, *Scenedesmus*) and macroscopic multicellular (e.g., *Macrocystis*, *Gracilaria*, *Sargassum*) algae (seaweeds), and a number of water and salt marsh plants such as cordgrass (*Spartina* spp.), reed (*Arundo*, *Phragmites*), bulrush (*Scirpus*), and water hyacinth (*Eichhornia*). Dry matter yields range between 5 and 75 Mg ha^{-1} $year^{-1}$. Water hyacinth is considered a nuisance plant in many inland waterways and is difficult to control, but is hardy and disease resistant. Many of the aquatic species are currently produced under much more intensive conditions, and generally for more valuable products than energy and fuels, for example, *Spirulina* for food protein or for antihistamine peptides used in the prevention of atherosclerosis (Spolaore *et al.*, 2006; Vo and Kim, 2013), although benefits of its use as a supplement for animal feeds are still in question (Holman and Malau-Aduli, 2013).

Algae and cyanobacteria represent a significant fraction (20–30%) of global photosynthetic productivity and are widely investigated for their energy and industrial product potential (Waterbury *et al.*, 1979; Spolaore *et al.*, 2006; Pisciotta *et al.*, 2010). High lipid concentrations in some strains of algae (up to 50% in *Nannochloropsis* and 60% in *Botryococcus braunii* (Scott *et al.*, 2010)) have encouraged research and commercial development into the production of biodiesel fuel from algal extracts and fermentation of algae for alcohol, biogas, and other products using algal production in open natural systems, ponds and raceways, as well as in highly engineered bioreactor systems (Sheehan *et al.*, 1998; Cheng *et al.*, 2013). Petroleum resources that supply current motor fuels and other energy demands predominantly originate from algal and zooplankton biomass deposited during periods of global warming approximately 90 and 150 Ma ago (Campbell, 1988). Interest in algae is also driven by perceived high productivities and the potential for carbon uptake and sequestration in mitigating carbon dioxide emissions from power plants. Single-day maximum productivities obtained in research trials are up to 50 g of dry matter per square meter per day, which if sustained throughout the year would equate to 183 Mg ha^{-1} $year^{-1}$, well above yields from the best producing C4 species. Commercial yields are unlikely to exceed approximately 80 metric tons dry matter per hectare per year (Scott *et al.*, 2010) although more optimistic estimates are frequently made. Sea-based floating membrane bioreactors have also been proposed to enable large-scale off-shore farming of algal biomass using municipal wastewaters as nutrient sources (Howell, 2009; Harris *et al.*, 2013).

Structure, Composition, and Properties of Biomass

Biomass is a chemically rich feedstock that can be used in its native form, converted into intermediate chemicals and materials for further downstream processing to final products, or converted directly to the final product. Composition varies by the type of feedstock, location of production, and by a number of other cultural attributes, but can be generally classified into organic and inorganic constituents all of which can be important in the conversion to energy, materials, and fuels. These

constituents can be further divided into a number of components and properties subject to international standards of analysis (Figure 1).

Fresh or crude biomass contains water as moisture and dry matter, the latter comprises organic constituents that are volatile under heating (volatile solids) and an inorganic fraction represented as ash. Moisture content influences the entire production chain due to its importance in determining the harvesting conditions, transportation modes and costs, conversion technology type and performance. For the processes involving thermal transformations (e.g., combustion), the organic fraction is typically classified into volatile matter (not to be confused with volatile solids) and fixed carbon, but combined these two fractions comprise most of the structural components of biomass (principally hemicellulose, cellulose, and lignin but also pectin and other cell wall polymers) and extractives (e.g., lipids in algae or oilseeds, sugars, starches, and terpenes and also many other compounds including some of the inorganic constituents). The ash consists typically of salts and other minerals, metals, and adventitious material, that is, materials not inherent in the biomass but added instead through handling and processing, such as soil accumulated during harvesting. Organic materials may also be adventitious, and alterations in the organic composition and structure can occur through degradation or decomposition of the feedstock during handling, storage, and processing. More fundamentally, the biomass can be characterized by its elemental composition that will contain essentially every natural element but more practically is limited to a smaller number of major elements with a large number of minor and trace elements at concentrations of significance, some of which will be important to industrial processing or energy conversion (e.g., lead, mercury, and other heavy metals). The design of any industrial system requires a careful analysis of the chemical and physical properties of the intended feedstock to evaluate influences on process operations and product quality.

The structure of biomass varies depending on the species and the tissue type. Microstructures of some higher plants (woods and grasses) are shown in Figures 2–4. The term 'wood' more specifically refers to the secondary xylem tissue arising from cell division in the vascular cambium (Hon and Shiraishi, 2001), but bark and other tissues are also generally included when referring to feedstock materials even though compositions can be widely different. Ash content, for example, is frequently higher in bark than in wood. Its distribution also varies in herbaceous species such as rice (Summers *et al.*, 2003). Woods are classified as softwoods and hardwoods. Tracheid and parenchyma cells are the principal types in softwoods, with tracheids in some comprising 90% of the wood volume. Hardwoods are more complex. Principal cell types in hardwoods are fibers, vessels, and parenchyma. Herbaceous species such as the grasses have tubular or solid stems (culm) divided into node and internode regions, the latter typically surrounded by leaf sheaths originating from the nodes. Algae constitute a highly diverse group of eukaryotic organisms that can be unicellular or multicellular and differ in fine structure compared with terrestrial green plants (Bouck, 1965). They range in size from microalgae under 5 μm (e.g., *Scenedesmus*) to the macroscopic giant kelp (*Macrocystis pyrifera*) exceeding 50 m in length. They also vary substantially in lipid, carbohydrate, nucleic acid, and protein composition (Sheehan *et al.*, 1998). Fresh-weight moisture is more than 65% and more commonly more than 85%; dry weight ash contents can exceed 30%; protein concentrations can approach

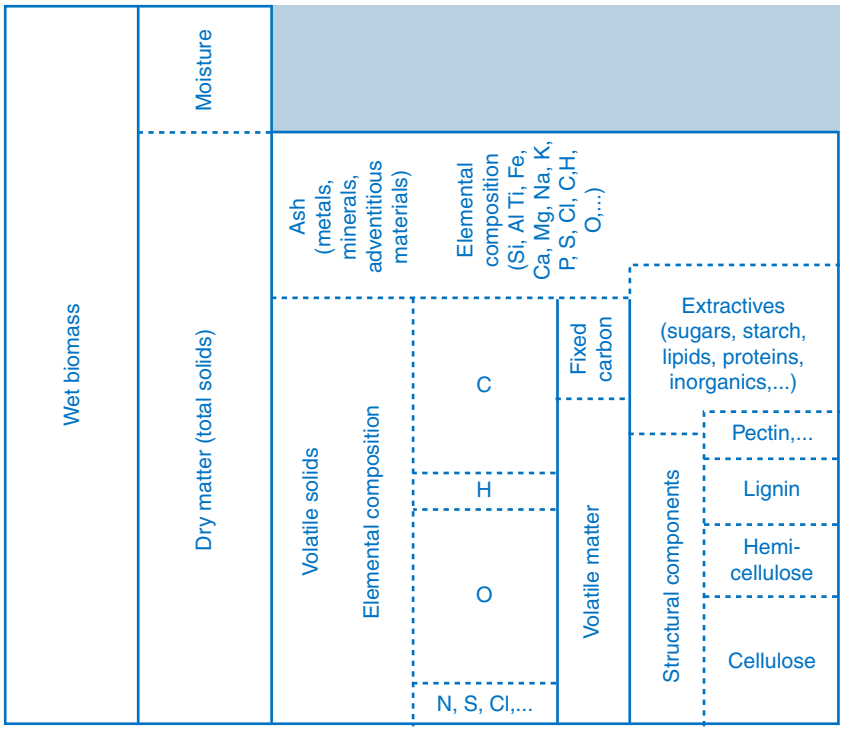

Figure 1 Biomass composition (dashed lines indicate variable concentrations).

half the dry weight; and lipid concentrations range up to 60% dry weight (Butler, 1931; Renaud *et al.*, 1999; Sheehan *et al.*, 1998). Cell wall components include cellulose, hemicelluloses, lignin, pectins, arabinogalactan proteins, extensin, carrageenan, agar, and in diatoms sculpted silica composites (Blumreisinger *et al.*, 1983; Abo-shady *et al.*, 1993; Domozych, 2011; Domozych *et al.*, 2012). The so-called blue-green algae (prokaryotic cyanobacteria) are now classified with the bacteria. Chitin (polymeric *N*-acetylglucosamine, also found in the exoskeletons of arthropods) rather than cellulose is the primary structural component of the cell wall among the true fungi (Blumenthal and Roseman, 1957; Sikkema and Lovett, 1984).

The dominant structural compounds making up the plant biomass are cellulose (six-carbon or C6 polymers) and hemicellulose (predominantly C5 polymers but including C6 species) produced via condensation polymerization of the monosaccharides (Chum and Baizer, 1985; Schultz and Taylor, 1989; Sudo *et al.*, 1989; Lynd, 1990; Wyman and Hinman, 1990; Hon and Shiraishi, 2001). The other primary structural components are lignins, aromatic polymers of variable structure derived in one proposed pathway from coniferyl, sinapyl, and *p*-coumaryl alcohols. The alcohols arise through the shikimic acid pathway, and are polymerized into lignin via free-radical reactions (Salisbury and Ross, 1992). Organic compounds in biomass also include proteins, triglycerides (fats and oils), terpenes (including isoprenes), waxes, cutin, suberin, phenolics, phytoalexins (antimicrobial compounds produced by the plant), flavonoids, betalains, alkaloids, and other secondary compounds as well as sugars and starch. Plants accumulate inorganic materials (ash), sometimes in concentrations exceeding those of the hemicellulose or lignin. The composition of wood can depend on the applied forces during growth ('reaction' wood). Compression wood typically has highly lignified tracheid walls, in contrast to tension wood with lower lignin concentrations.

Cellulose is a linear crystalline polysaccharide of β-D-glucopyranose units linked with (1–4) glycosidic bonds. Cellulose serves as a framework substance, making up 40–50% of wood. In the cell wall, cellulose exists in the form of thin threads or microfibrils, each 2–5 nm wide in wood, but up to 30 nm wide in algae (*Valonia*). The polymer is formed from repeating units of cellobiose, a disaccharide of β-linked glucose moieties (**Figure 5**). The structure of cellulose renders it highly insoluble and resistant to biochemical degradation. The α-linked disaccharide of glucose forms starch (**Figure 6**). Starch is an amorphous material, and as such is more readily degraded by biochemical means than is cellulose and hence the relative ease of fermenting starch to ethanol whereas cellulose requires substantial pretreatment to deconstruct it before fermentation.

Hemicelluloses are matrix substances laid down between cellulose microfibrils. They are polysaccharides of variable

composition containing both five- (including xylose and arabinose) and six-carbon (including galactose, glucose, and mannose) monosaccharide units. Like starch, hemicelluloses are mostly amorphous, making them more readily hydrolysable than cellulose. Hemicelluloses constitute 20–30% of wood, generally with higher concentrations in hardwoods than softwoods. Hemicelluloses also constitute 20–30% of dry matter in most other biomass. Partial structures for the primary forms of hemicellulose in hardwood and softwood are shown in Figure 7.

Lignin is the encrusting substance ('glue') solidifying the cell wall. Lignin is an irregular polymer of phenylpropane units and the structure varies among different plants. Lignin is thought to occur through the enzymatic dehydrogenation of phenylpropanes followed by radical coupling (Hon and Shiraishi, 2001). Softwood lignin is composed principally of guaiacyl units stemming from the precursor *trans*-coniferyl alcohol (Figure 8). Hardwood lignin is composed mostly of guaiacyl and syringyl units derived from *trans*-coniferyl and *trans*-sinapyl alcohols. Grass lignin contains *p*-hydroxyphenyl units deriving from *trans*-*p*-coumaryl alcohol. Almost all plants contain all three guaiacyl, syringyl, and *p*-hydroxyphenyl units in lignin. A partial structure of softwood lignin is shown in Figure 9.

Partial compositions of selected biomass materials are listed in Table 3. The four materials – Monterey pine (*Pinus radiata*, a softwood), eastern cottonwood (*Populus deltoides*, a hardwood), sugarcane bagasse (from *Saccharum* spp.), and wheat straw (from *Triticum aestivum* var. *Thunderbird*) – were analyzed as reference materials for the purposes of providing reference characterizations of industrial and energy feedstocks (NIST, 2003).

Plants producing large amounts of free sugars, such as sugarcane and sweet sorghum, are attractive as feedstocks for ethanol fermentation, as are starch crops such as maize (corn) and other grains. Current attention is focused on the fermentation of the cellulosic components because of the perceived economic and energetic advantages for large-scale liquid fuel production. Cellulose and hemicellulose are not fermentable by conventional means, as more aggressive pretreatment and hydrolysis must precede the fermentation step. Lignins are not yet generally considered fermentable, and thermochemical means are usually proposed for their conversion to fuels. Typically, 60–80% of the biomass feedstock mass is ultimately fermentable based on cellulose and hemicellulose (holocellulose) concentrations.

Oil crops such as rape and canola, soybean, sunflower, safflower, algae, and others have been widely investigated for

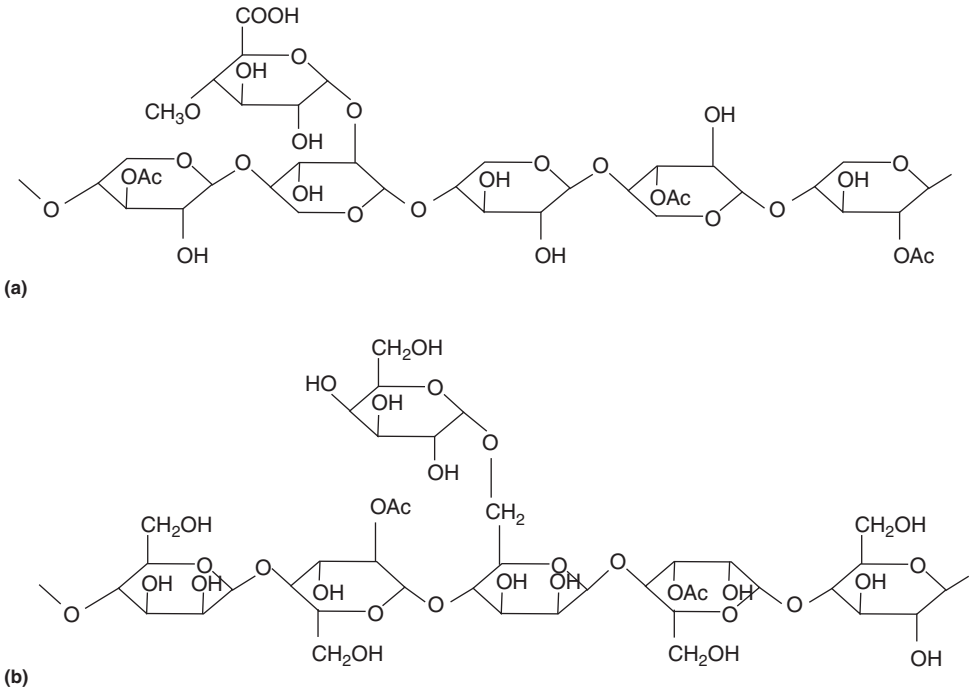

Figure 7 Partial structures of the principal hemicelluloses in wood (Hon and Shiraishi, 2001): (a) *O*-acetyl-4-*O*-methylglucuronoxylan from hardwood; (b) O-acetyl-galactoglucomannan from softwood. Ac = acetyl group.

their potential in producing diesel fuel substitutes (commonly referred to as 'biodiesel'). Although raw plant oils are not generally satisfactory as fuels for diesel-type (compression-ignited) engines, methyl and ethyl esters formed by reacting the oil with an alcohol (methanol or ethanol) have lower viscosity and improved injection and combustion properties making them suitable for engine use (Peterson *et al.*, 1992). Other crops, such as *Euphorbia*, have been investigated for direct production of hydrocarbons (Nishimura *et al.*, 1977; Nemethy *et al.*, 1981).

Roughly half of the plant organic matter is carbon, the rest being made up of 5–7% hydrogen, 30–50% oxygen, along with nitrogen, sulfur, chlorine, and other elements (Jenkins and Ebeling, 1985; Jenkins *et al.*, 1998). The ash or inorganic fraction of biomass may account for more than 30% of the dry mass in some cases (e.g., animal manures and other waste materials, some algae). Temperate region woods typically have ash contents below 1%, whereas some tropical woods contain up to 5% ash (Chum and Baizer, 1985). Leaves and young tissues contain more ash than mature wood. Cereal grain straws, hulls (husks), and other agricultural biomass have ash contents ranging up to approximately 25% of the dry mass. The amount of ash in a biomass material, and the composition of the ash are important for the selection of the conversion technology. As noted earlier in the Section Types of Biomass, alkali metals (especially the macronutrient potassium) in the ash of many agricultural residues can cause slagging and boiler fouling and corrosion in the case of direct firing as a result of high temperature reactions with silica and other minerals. Chlorine is important in corrosion and as a facilitator in the alkali reactions leading to deposition in boilers. Biochemical methods avoid this problem because of the lower temperatures involved although corrosion can still be of concern. Other methods, such as supercritical water oxidation, in which the oxidation is carried out at a relatively low temperature but high pressure, may suffer less from ash reactions although salts can be an issue, but such processes are not yet commercial. In certain circumstances, fouling is reduced by the extraction of the offending elements before introducing the fuel to the boiler. Such is the case of sugarcane

Each value is mean from round-robin testing of approximately 20 laboratories.

bagasse, commonly used as a fuel in the sugar industry, but which has passed through the sugar extraction step and had most of the alkali leached in the process. Direct firing of cane trash, currently under investigation for increasing the power generation from the cane industry, does not extract these elements, and may suffer from deposition common to straws and other high ash, high alkali biomass fuels.

The energy content or heating value (heat of combustion) of biomass can be partially correlated with ash concentration. Woods with less than 1% ash typically have heating values near 20 MJ kg^{-1}. Each 1% increase in ash translates roughly into a decrease of 0.2 MJ kg^{-1} (Jenkins, 1989) because ash does not contribute substantially to the overall heat released by combustion, although elements in the ash may be catalytic to thermal decomposition. Heating values can also be correlated to carbon concentration, with each 1% increase in carbon elevating the heating value by approximately 0.39 MJ kg^{-1}, a result identical to that found by Shafizadeh (1981) for woods and wood pyrolysis products. The heating value relates to the amount of oxygen required for complete combustion, with 14 022 J released for each gram of oxygen consumed (Shafizadeh, 1981). Cellulose has a smaller heating value (17.53 MJ kg^{-1}) than lignin (26.7 MJ kg^{-1}) because of its higher degree of oxidation. Other compounds, such as hydrocarbons, with lower degrees of oxidation or containing no oxygen tend to raise the heating value of the biomass.

Proximate and elemental compositions and heating values for selected biomass are listed in **Table 4**. The heating value shown in the table is the constant volume higher heating value that is one of four that can be defined based on whether the test is carried out at constant pressure or constant volume and whether water produced from the hydrogen in the biomass is in the vapor or liquid phase at the end of the test (Jenkins, 1989). Wheat straw and sugarcane bagasse listed in **Table 4** are not the same samples listed in **Table 3** and hence have different compositions. The proximate analysis yields ash content and the fraction referred to as volatile matter (**Figure 1**) evolved during a short heating at 950 °C in a nonoxidizing atmosphere representing pyrolysis. The difference between the total dry matter and the sum of ash and volatile matter is fixed carbon (essentially charcoal). The ultimate analysis yields elemental concentrations of carbon, hydrogen, nitrogen, and sulfur, with oxygen usually determined by difference. Although not part of the standard for ultimate analysis, chlorine is also sometimes analyzed due to its importance in many conversion systems. The Jose tall wheat grass listed in the table was grown as a phytoremediation crop under saline conditions, and has a high Cl content.

Logistical Supply Chains

The use of biomass for industrial products and energy typically requires a supply chain of multiple operations to deliver biomass feedstock or biomass-derived intermediates from the site of production to the conversion facility and then the finished product into final demand (**Figure 10**). For food processing facilities, lumber mills, wastewater treatment plants, dairies, and other animal operations, the supply chain may be relatively simple due to the generation of the feedstock on-site.

For crop and forest residues and energy crops, supply operations upstream of the conversion facility will typically include collection or harvesting, packaging and processing such as baling, pelleting or grinding, loading and unloading onto transport vehicles, transportation on roads, rail, river or marine routes, and in most cases storage, possibly at one or more intermediate sites (depots) in addition to the primary site of conversion. Densification of the bulk biomass may be preferred for the purposes of achieving high transportation payloads on trucks and other vehicles but contributes to the cost of processing. Whether the cost can be justified depends in part on transport distance and other factors associated with the handling and use of the feedstock and the cost of transport otherwise. Conversion into pyrolysis oils, sugars, and other intermediate products at depots or other satellite facilities may also be considered for logistical purposes to reduce the total costs of feedstock transportation to larger central facilities for final processing and production.

Drying to reduce moisture content may be needed, especially for feedstocks intended for many types of thermochemical conversion facilities. For some facilities, for example, biochemical conversion facilities using fermentation systems, the moisture in feedstock may be an important contribution toward meeting the overall process water demands and may enhance conversion but adds to transportation costs and increases the risk of spoilage during handling.

The costs associated with feedstock supply, conversion, and the distribution of finished products influence the optimal size of a conversion facility (Jenkins, 1997). Economies of scale typically exist for capital and operating costs so that as the production capacity or size increases, these costs typically do not increase in the same proportion and the cost per unit of product output decreases. However, as the size of the facility increases, the feedstock demand increases as well, and for distributed feedstocks such as crop and forest residues and purpose-grown crops, this means the supply region will generally increase unless crop productivity and yields can be increased to compensate for the added supply needs. Transportation costs, therefore, increase, but not generally in direct proportion to the facility size. These competing effects lead to a system size at which either total cost of production is minimized (**Figure 11**) or profit is maximized depending on the objective function. For example, economies of scale in the capital and operating costs of facilities to generate electricity (power plants) from biomass coupled with increasing costs of feedstock acquisition yield a minimum in the levelized (amortized) cost of energy from the plant (**Figure 11**). The scaling in capital and operating cost may take a functional form such as

$$\frac{C}{C_o} = \left(\frac{M}{M_o}\right)^s \quad [3]$$

where C is the cost; M is the facility size or capacity; the subscript denotes a reference facility of known cost and size; and s is the scaling factor that specifies how cost varies with size. The optimum size is sensitive to the scaling relationship and the value of s. The two cases of **Figure 11** were derived for s is constant for all sizes and s is variable and increasing with size to account for increasing risk as the facility size becomes very

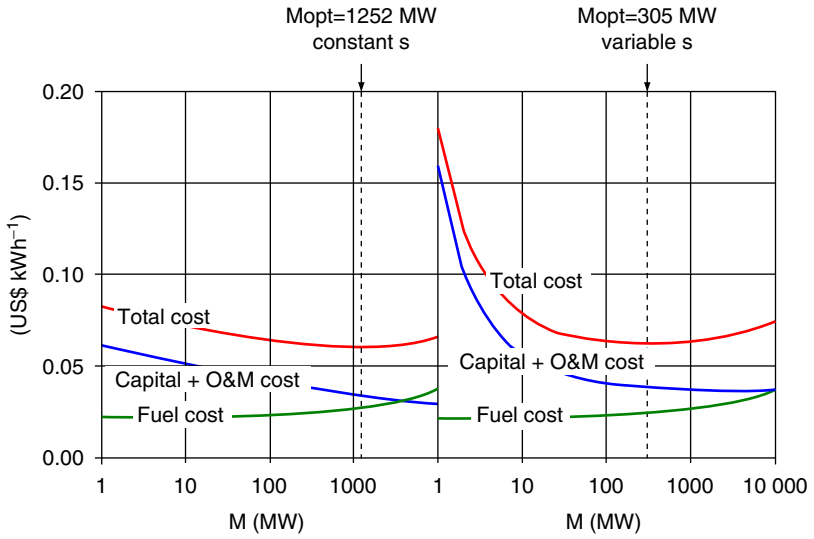

Figure 11 Economy of scale and capacity optimization in biomass conversion (Jenkins, 1997).

large. The cost–size dependence for regionally distributed feedstock typically follows a different relationship, contributing an increasing cost per unit of production as the facility scale increases (Figure 11) (Jenkins, 1997). The estimated cost of power generation is plotted in Figure 11 against the facility size on a logarithmic scale, which masks to some degree the broad range around the optimum in which cost does not vary substantially, a characteristic of larger size facilities. The optimal sizes in both examples are quite large for biomass power generators and few facilities approach these sizes in practice. To some extent, this is due to regulations that also affect facility siting and permitting. In California and the US, for example, new facilities must undergo a siting review when the size exceeds 50 or 80 MW electrical capacity and this adds to the cost of facility development (Jenkins, 1997).

Consideration of the feedstock properties and availability, the regional product markets, and the costs and prices associated with production and sales are important to the size,

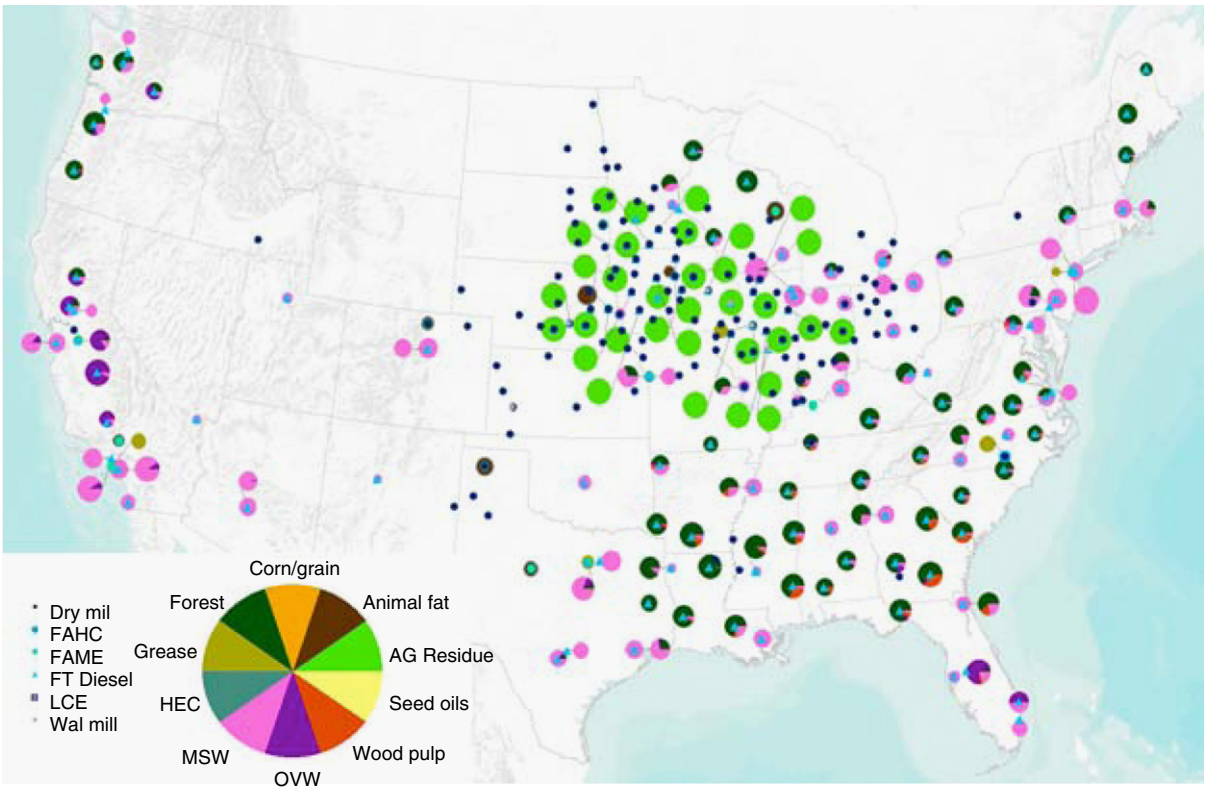

Figure 12 Optimized potential biorefinery locations in the US identified through geospatial modeling of biomass resources, supply infrastructure, and fuel demand (Parker, 2011).

type, and location of conversion or production facilities. Geospatial modeling using resource location data to give the spatial distribution of feedstock coupled with technoeconomic models of conversion facilities and distribution models of finished product have been used, for example, to project policy outcomes for biorefinery development in the US and to speculate on the optimized structure of the future industry (**Figure 12**) (Parker *et al.*, 2010; Tittmann *et al.*, 2010; Parker, 2011).

Chemicals and Materials from Biomass

Products from biomass originate both from direct use or extraction of materials from the parent tissues and via conversion of the biomass to alternate forms. In related bioprocessing, the biomass can serve as a substrate by which the cellular mechanisms are used by another organism to express the desired product, for example, the transient expression of a protein through the process of agroinfiltration (Joh and Vander-Gheynst, 2006).

The potential to produce a much larger range of chemicals, materials, and other products from biomass has been widely recognized, including direct replacement of products now synthesized from petroleum, natural gas, and other nonrenewable resources (Johnson, 2007). Biobased plastics, lubricants, solvents, surfactants, composites, and other products are increasing in market shares as technology improves, new markets are developed, and demand increases for more sustainable or 'green' products (BIOCHEM, 2010). Global production of bioplastics is projected to increase five-fold by 2016 to close to 6 million metric tons compared with the production in 2011, although in this case demand for biodegradable plastics does not appear to be the major driver of growth as only 13% of the total is anticipated to be in polymers of this type (European Bioplastics, 2013). Biobased polyethylene terephthalate (PET) is likely to make up the largest fraction (greater than 40%) of the total. Other drivers, such as displacement of petroleum and reduced greenhouse gas emissions, plus economic and market factors account for the increasing demand of biologically derived materials. For example, in the making of riboflavin (vitamin B2), single-step instead of six-step processing, increased productivity, and reduction in cost are quoted as the main forces in the adoption of a biobased process (Johnson, 2007). Similar rationale exists for the production of antibiotics and acrylamide monomers (Johnson, 2007; Scott *et al.*, 2007). Improved processes and efficiencies in the manufacturing of biobased intermediates and final products are the subject of substantial research, such as the use of biomass-derived furans in the catalytic production of *p*-xylene that is, in turn, used to make terephthalic acid, a monomer for PET (polyester) plastics (Williams *et al.*, 2012), or the conversion of biomass-derived carbohydrates to chemical feedstocks, such as alkenes and aromatics, that are now principally produced from petroleum (Arceo *et al.*, 2009; Arceo *et al.*, 2010).

Agriculture and forestry have long supplied materials other than food and feed for construction, pulp and paper, textiles,

medicine, cosmetics, soaps, and other uses, and the production of materials such as plastics from biomass is not new, although many new and novel chemicals are now becoming available. Crude plastics were historically made from natural proteins, such as those from blood, egg, and milk. Goodyear's vulcanization of natural rubber beginning in 1838 provided a pathway to thermoset materials (Richardson, 2010). Shellac was produced by dissolving the natural resin secreted by the lac bug in ethanol (Patel *et al.*, 2013). The conversion of cellulose to nitrocellulose by the addition of nitric acid was discovered in 1846 and used for the preparation of guncotton, and nitrocellulose modified by camphor as a plasticizer was being used by 1889 for photographic film by Eastman Kodak (Michel, 2006; PHS, 2013a). Nitrocellulose is now applied in such diverse uses as membranes for protein immobilization and analysis and solid-rocket motors. The compound (as celluloid) was also famously used in the attempted replacement of natural ivory for billiard balls but the balls had a tendency to explode on impact. Cellulose acetate, the acetate ester of cellulose, was first prepared in 1865 and is still widely used for plastic films and other applications (PHS, 2013b). Viscose, a polymer of wood pulp, was patented in 1892 and the process for making cellophane, a viscose plastic film produced by dissolving cellulose in alkali and carbon disulfide was established by 1913 (PHS, 2013c). Despite the pollution issues associated with disulfide in the manufacturing process, cellophane is biodegradable and has remained in continuous production since the 1930s especially for food packaging (Rojo *et al.*, 2010; PHS, 2013c). Rayon fiber used in textiles is made through a similar process.

Comprehensive studies have examined candidate materials from sugars, synthesis gases (syngas), and lignin, all derived from biomass (Werpy and Petersen, 2004; Holladay *et al.*, 2007). The study by Werpy and Petersen (2004) identified an initial set of 300 possible building-block chemicals from sugars and syngas in integrated biorefineries. Such biorefineries conceptually involve various processing operations within the same production facility (**Figure 13**) for the manufacturing of multiple value-added products, similar to but potentially more complex than modern petroleum refineries that produce a variety of commodity chemicals and fuels (Johnson, 2007). Screening criteria for the chemical selection included feedstock cost, estimated processing costs, market information, and compatibility with current and projected future refining operations. From this initial set, a foundational suite of chemicals was selected based on more strategic criteria (direct product replacement, novel products, and building-block intermediates) and the value chains associated with processing to products for final demand (**Figure 14**). The resulting network of product interactions has been widely referenced in relation to potential biorefinery design and opportunities for products from biomass. The final suite includes compounds with carbon numbers (number of carbon atoms in the molecule) ranging from C1 to C6 (**Table 5**). These compounds have multiple functionality for further downstream conversion and could be produced from both lignocellulose and starch in making sugars or syngas as intermediate chemical platforms, some of the principal platforms under development for energy and products from biomass. The study by Holladay *et al.* (2007) later identified other products from lignin using the criteria based on technical difficulty in production, market potential, market risk, building-block utility, and whether the product could be made as a single compound or would be present in a mixture with other compounds (**Table 5**).

As illustrated in **Figure 14**, a wide spectrum of products can be produced from biomass to serve multiple markets in what is loosely classified a biobased economy. These products can range from higher value, generally lower production and sales volume chemicals such as pharmaceuticals, food additives, and cosmetics, to lower value, higher volume chemicals and materials such as biobased plastics and composites, chemical feedstocks, fuels, and environmental products such as biochar or black carbon now being investigated for its agronomic

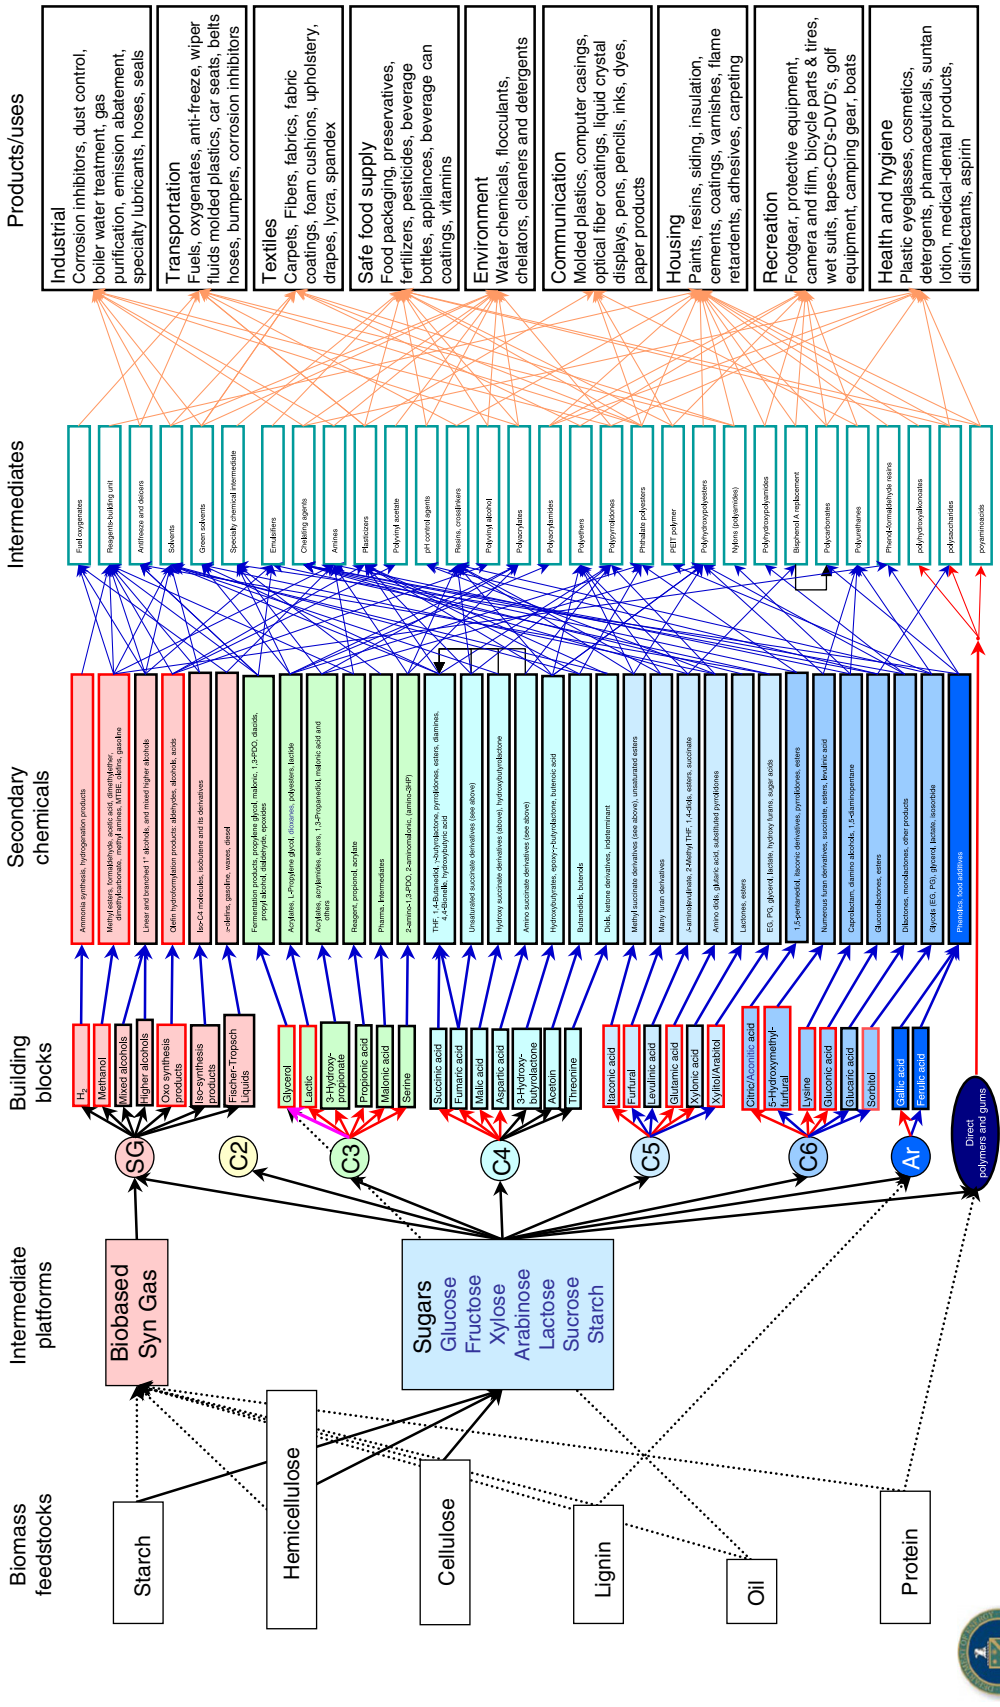

Figure 14 Chemical platforms for biobased products from biomass feedstocks (Werpy and Petersen, 2004).

Table 5 Building-block chemicals and products from sugars, syngas, and lignin (Werpy and Petersen, 2004; Holladay *et al.*, 2007)

Source	*Chemical*
Sugars/ syngas	C1: Carbon monoxide (CO) and hydrogen (H_2) (syngas) C3: Glycerol, 3 hydroxypropionic acid, lactic acid, malonic acid, propionic acid, and serine C4: Acetoin, aspartic-acid, fumaric acid, 3-hydroxbutyrolactone, malic-acid, succinic acid, and threonine C5: Arbinitol, furfural, glutamic acid, itaconic acid, levulinic acid, proline, xylitol, and xylonic acid C6: Aconitic acid, citric acid, 2,5 furan dicarboxylic acid, glucaric acid, lysine, levoglucosan, and sorbitol
Lignin	Process heat and power, syngas, methanol, dimethyl ether (DME), ethanol, mixed alcohols, hydrocarbons (Fischer–Tropsch liquids), C1 – C7 hydrocarbon or oxygenates, alkylates (benzene, toluene, xylene, and higher), cyclohexane, styrenes, biphenyls, phenol, substituted phenols, catchols, cresols resorcinols, eugenol, syringols, coniferols, guaiacols, vanillin, vanilic acid, DMSO, aromatic acids, aliphatic acids, syringaldhyde and aldehydes, quinones, cyclohexanol/al, beta-keto-adipate, carbon fiber, polyelectrolites, polymer alloys, fillers, polymer extenders, substituted lignins (carbonylated, ethoxylated, carboxylated, epoxidized, and esterified), thermoset resins, composites, formaldehyde-free adhesives and binders, wood preservatives, nutraceuticals and drugs, and mixed aromatic polyols

utility in soils and as a means to sequester carbon (BIOCHEM, 2010; Keiluweit *et al.*, 2010; Woolf *et al.*, 2010).

Biobased plastics (bioplastics) constitute the class of manufactured plastics that are either entirely or partially composed of biologically derived materials, that is, biomass. Plastics certified as compostable frequently contain a high proportion of biobased materials but not all biobased polymers are biodegradable (BIOCHEM, 2010). Current bioplastics include the bulk materials polylactic acid (PLA), polyamides (nylon), polyhydroxyalkanoates, polybutyleneterephthalate and PET and polyethylene from among a larger number of thermoplastics, and polyurethane from among the thermosetting materials. These are typically prepared from sugars and starches or from processing residues (e.g., lignin). PLA is principally made from plant sugars polymerized through a process of fermentation. Corn is a major source. Biobased succinic acid, a precursor to various bioplastics, can be produced from glucose and sucrose sugars and is a replacement for petroleum-based adipic acid (Chimirri *et al.*, 2010; Liang *et al.*, 2013).

Composite materials are standard products of the wood industry (e.g., particleboard) but a wider variety of biomass feedstocks are now being investigated for their application in this market, including woody and herbaceous biomass such as *Eucalyptus*, Athel (*Tamarix* aphylla), and Jose tall wheatgrass (*A.* elongatum) used also in phytoremediation of salt-affected soils (Pan *et al.*, 2007; Zheng *et al.*, 2006, 2007a). Particleboards made from saline wood generally had equal or better mechanical qualities compared with boards made from more conventional nonsaline wood materials (Zheng *et al.*, 2006, 2007a).

Nanomaterials from biomass are also being investigated for a wide variety of applications. Low-cost carbon fiber production has been the subject of much interest especially in the wake of recent legislation to increase vehicle fuel economy standards in the US that add motivation to finding new lightweight materials with good strength and from sustainable sources. Toward this purpose, lignin has been investigated for its use in producing carbon fiber but is required to be of high purity with a narrow molecular weight distribution, and greater research is needed in the refining of this potential feedstock (Baker and Rials, 2013). Carbon nanofibers, nanotubes, graphenes, and other materials have also been investigated for use in energy storage devices, particularly ultra- and supercapacitors. Carbon nanosheets for use in high energy density supercapacitors have been made from hemp bast fibers, yielding a maximum energy density of 12 Wh kg^{-1} and 8–10 Wh kg^{-1} after charge times of less than 6 s, comparable to or greater than the conventional activated carbons (Wang *et al.*, 2013b). The multilayered structure of the feedstock biomass in this case provides a unique starting morphology for producing the carbon sheets.

Biobased lubricants and solvents are similarly classified as being comprised entirely or in part from biomass. Biobased lubricants predate petroleum-based compounds and are either vegetable oil-based or manufactured from modified oils including synthetic esters made from mineral oil-based products (BIOCHEM, 2010). Finished products can be biodegradable with improved environmental properties and lower toxicity allowing use in more sensitive environments. Canola and a number of other vegetable oils have been investigated as feedstocks in the production of more environmentally benign motor oils for engines (Johnson *et al.*, 2002). Solvents are used in many different applications, such as additives in paints, degreasing agents, pharmaceutical extractions, stripping agents, and cleaners. A key property of some biobased solvents is their low emission of volatile organic compounds that are both direct health hazards and contribute to reduced air quality, for example, in reactions with oxides of nitrogen or NO_x in the formation of tropospheric ozone, a breathing hazard and regulated air pollutant (U.S. EPA, 2013). The fatty acid methyl ester of soy oil made from soybeans, in addition to its use as biodiesel, is also a biosolvent, as are lactate esters, limonene, and other citrus terpenes. Although limonene (as D-, L-, and DL-limonene), for example, is listed as a generally recognized as safe synthetic flavoring substance by the US Food and Drug Administration (CFR, 2006), and high-purity products may generally prove of low allergenic properties, oxidized products (such as obtained by exposing to air for prolonged periods) have been shown to produce sensitivity in animals (Karlberg *et al.*, 1991) and safety properties need to be carefully considered in application.

Plant oils are also used in the production of surfactants – chemicals that lower the surface tension of liquids to allow better mixing. By definition, biosurfactants have at least one of the hydrophobic or hydrophilic groups associated with the surfactant molecule from a biobased source and so can also be either entirely or partially derived from biomass.

Feedstocks include palm oil, sorbitol, sucrose, glucose, and animal fats such as tallow. Surfactants are common ingredients in detergents but are used in a wide range of other products including agricultural chemicals, textiles, paints, and lubricants (BIOCHEM, 2010), and nonionic surfactants have been employed in the enzymatic hydrolysis of biomass as pretreatment for fermentation and biofuel production (Zheng *et al.*, 2007b).

Biochar or black carbon from biomass has received much attention in recent years for its perceived utility in maintaining soil carbon stocks and soil fertility. Although carbon produced from biomass in various stages of activation has long served for water treatment and environmental remediation, the discovery of the *terra preta do índio* soils in the Amazon stimulated new research related to understanding the properties of carbons for soil applications including chars produced in conjunction with energy conversion, especially biomass pyrolysis but also thermal gasification. The potential new market in biocarbons is fortuitous also for thermochemical energy conversion systems where char coproducts have in the past posed a disposal problem given the limited capacity of the activated carbon markets. The terra preta soils, which originate from pre-Columbian times and accumulated charcoal, bone, and manure as part of kitchen middens from food preparation and other activities, have been shown to have lower greenhouse gas emissions (as CO_2) per unit of carbon in the soil compared with similar soils with low or no black carbon (Liang *et al.*, 2010). In a study of black carbon from 12 different biomass feedstocks including hardwoods, softwoods, algal digestate, walnut shell, and turkey litter, char surface area, an important measure of sorptive properties, increased with charring temperature whereas chemical functionality could be separated into wood and nonwood feedstock groups (Mukome *et al.*, 2013). The presence of carbonate and chloride salts increased the basicity of chars from nonwood feedstock. Agronomic properties and impacts can be related to feedstock composition (Mukome *et al.*, 2013). Biochar applications to soils may also reduce the overall lifecycle greenhouse gas emissions for bioenergy systems (Gaunt and Lehmann, 2008).

Energy and materials from biomass frequently compete for common resources, hence in addition to lifecycle environmental concerns, debate also arises over the highest and the best use of biomass. Policies favoring one use over another can introduce economic distortions, as in the food-versus-fuel debate where both sectors may receive government incentives or subsidies but without substantial coordination aimed at improving the overall sustainability. Given the limited supplies of biomass, the potential to extract multiple products through integrated biorefining (cascading the biomass use) has been suggested as a way to maximize the value of the resource (Keegan *et al.*, 2013). Such practice already exists in both the forestry and agriculture sectors, for example, in pulp and paper manufacturing and sugar milling in which high-value materials are extracted before processing residues (e.g., lignin from wood or bagasse from sugarcane) are utilized for energy conversion. As energy values increase, however, economic distinctions tend to disappear in many cases, shifting focus onto other performance metrics as indicators of social good. Greenhouse gas emissions may be reduced through the production of biomaterials, many of which can sequester renewable carbon over long periods of time in addition to displacing fossil emissions from petroleum or other nonrenewable resources. Significant opportunities exist to improve material flows through the society to meet both material and energy needs. Just as integrated technologies may improve the economic benefits for energy and materials from biomass, policies that address system-level resource management effects may realize a greater social benefit. Uncertainties remain in the assessment of net benefits for both materials and energy conversion from agricultural feedstocks and distinct needs exist for improved information.

Energy from Biomass

The potential for biomass to supply much larger amounts of useful energy has stimulated substantial research and development into systems to convert biomass into the principal forms of heat, electricity, and solid, liquid, and gaseous fuels (Bungay, 1981; Hall and Overend, 1987; Kitani and Hall, 1989; Klass, 1998; Brown, 2003). Although substantial debate continues over the sustainability of large-scale bioenergy development, so do advances continue across a wide range of conversion technologies and systems to improve the overall efficiencies and fuel yields, fuel properties, lifecycle costs, and environmental performance.

Three principal routes exist for converting biomass to energy: (1) thermochemical, (2) biochemical, and (3) physicochemical. In practice, combinations of two or more of these routes may be used in the generation of the final product or products. Chemical or biological catalysts are employed in many cases. Thermochemical conversion includes combustion, thermal gasification, and pyrolysis along with a number of variants involving microwave, plasma arc, supercritical fluid, hydrothermal, and other processing techniques (Brown, 2011). Products include heat, fuel gases, liquids, and solids. Thermochemical techniques tend to be of high rate and relatively nonselective for individual biomass components in that the chemically complex biomass is substantially degraded into simple compounds (e.g., CO, CO_2, H_2, and H_2O), which may later be reassembled into more complex compounds through either chemical or biological processing (Chum and Baizer, 1985). Biochemical conversion includes fermentation to produce alcohols (ethanol being perhaps the best known), fuel gases (such as methane by anaerobic digestion), acids, and other chemicals (Klass, 1998). Among the physicochemical methods are alkaline and acid processes, esterification, mechanical milling, steam and ammonia freeze explosion and other explosive decompression processes, and pressing and extrusion, many times in combination with a biochemical or thermochemical reaction process. One major process under this category is vegetable oil extraction and esterification to manufacture biodiesel as a substitute for engine fuel. Biochemical and physicochemical processes in general are intended to be more selective for biomass components and higher value products, although thermochemical routes can also be used, as in the indirect production of methanol via thermal gasification (Hos and Groeneveld, 1987). There are other means of producing useful energy from biomass, such as biophotolysis for the production of hydrogen by plants

(Bungay, 1981), and other direct hydrogen routes (Cortright *et al.*, 2002), but these are not yet demonstrated on a commercial scale. Ethanol is already produced on a large scale as a biofuel, mostly for light-duty automotive use including as an oxygenate blendstock for motor gasoline as well as in higher concentrations for flexible fuel (FlexFuel) and neat (100%) fuel vehicles. Hydrocarbon liquids from biomass are of particular interest due to their similarity to current gasoline, diesel, and aviation fuels and their fungibility in existing fuel transportation and distribution systems such as pipelines. These and other so-called drop-in biofuels avoid the need for new infrastructure or the use of more expensive truck transport for large-scale application.

Thermochemical routes generally involve the heating and thermal decomposition of feedstock biomass to compounds that can either be directly used or reacted to produce other and potentially more valuable chemicals and fuels. Gasification and pyrolysis are thermochemical approaches that involve thermolysis of the feedstock to intermediate gases (e.g., CO and H_2 as synthesis gas or syngas) and liquids (e.g., biocrude) that can be burned directly, chemically synthesized into drop-in liquid fuels along with a wide variety of other fuels including methane, hydrogen, methanol, and dimethylether, or fermented biochemically to alcohols. These thermal processes can also produce biochar (see the discussion on materials from biomass above). Torrefaction is a light pyrolysis that typically is carried out as a pretreatment at temperatures between approximately 200 and 300 °C to produce a carbonized feedstock or biochar with improved grindability, densification, and other handling characteristics. Biochar production can add coproduct value to gasification, pyrolysis, and other thermochemical conversion processes although there remain many uncertainties regarding its value for these purposes. Intermediates such as biocrude produced through pyrolysis and lipids extracted from algae or oil seeds (vegetable oils) can be hydrotreated through the addition of hydrogen for upgrading to renewable diesels and other hydrocarbons. Combustion of the feedstock generates heat which can then be used in the generation of electricity or process steam and hot water, and is historically the largest energy use of biomass.

Biochemical routes, predominantly fermentation, rely principally on microbes (yeasts, bacteria, or fungi) for the conversion to useful fuels and chemicals. In most instances, hydrolysis of structural polymers (starch, hemicellulose, and cellulose, see above) through enzymatic or chemical means, possibly in combination with thermal or mechanical pretreatment, is necessary to generate the sugars or other simpler compounds upon which the microbes feed. Starch and sugar fermentation by yeast is well known and has long been used in making beverage alcohol (ethanol) and is currently used in producing most of the world's fuel alcohol from corn (maize) and sugarcane. The use of lignocellulosic biomass is less well developed and the subject of much research directed at improving hydrolysis, particularly enzymatic hydrolysis, of both the hemicellulose and cellulose fractions and simultaneous cofermentation of the resulting five and six-carbon sugars for which recombinant organisms have also been developed to work in association with or in place of yeast. Lignin is mostly recalcitrant to biological conversion and is often considered for use as boiler fuel in making process heat or steam (such as that used in distilling the alcohol) and electricity for the biorefinery but higher economic value may reside in fuel products if effective conversion techniques can be developed, for example, gasification to syngas for subsequent catalytic conversion to substitute natural gas or liquid fuels. Anaerobic digestion is another type of fermentation that typically uses mixed populations of bacteria to digest biomass to make biogas, a multicomponent gas consisting mostly of methane (CH_4, the major component of natural gas) and CO_2 with other more minor species including hydrogen sulfide (H_2S). Sulfide removal is typically needed before the use of biogas in engines especially those employing catalytic aftertreatment of combustion products for control of oxides of nitrogen (NO_x) and other air pollutants. Anaerobic digestion is commonly used in waste water treatment facilities and is becoming more common for managing animal wastes in concentrated animal feeding operations such as dairies and hog and poultry farms. Biogas is used as engine and boiler fuel, sometimes in combined heat and power (CHP) operations, such as for cheese making at the dairy. Biogas can be upgraded to pipeline quality methane to complement natural gas or for use as vehicle fuel as compressed natural gas (CNG) or liquefied natural gas (LNG), and can serve as chemical feedstock. Biogas has also been used in microturbines and for fuel cells for distributed power applications. Landfill gas is a biogas that is produced by the anaerobic decomposition of organics in solid waste landfills and is recovered for electricity generation and other energy purposes and to reduce hazardous migration of the gas into nearby structures.

Physicochemical processes are used in the making of biodiesel, a product of the catalyzed reaction between an oil, such as the vegetable oil, and an alcohol, such as methanol or ethanol, all of which can be produced from biomass. In the conventional biodiesel process, triacylglycerides that make up vegetable oils and other FOG are converted by transesterification into long-chain esters and coproduct glycerol. The esters (biodiesel) have lower viscosity than the original vegetable oil and have better injection and spray properties for use in diesel engines. Biodiesel can also be produced using enzymatic techniques. Coproduct markets for glycerol exist in soaps, cosmetics, and many other products but the potentially large production of fuel could saturate these markets so that additional uses are being investigated, including production of other fuels.

Industrial facilities to produce fuels and chemicals from biomass are typically classified as biorefineries. Integrated biorefineries can include multiple processing operations in making a suite of products from the same production facility, similar to modern petroleum refineries (**Figure 15**). Biofuels are often classified as first generation, second generation, and beyond, the terms intended to convey the development status and to some extent the perceived sustainability of the production systems although there are not always clear distinctions. First-generation biofuels include ethanol from starch and sugar as well as biodiesel, both mostly from food crops, but may also include biogas, syngas, and pyrolytic biooil. Second-generation biofuels include ethanol, hydrocarbons, and other fuels produced from lignocellulosic and algal feedstocks. Later generations are associated with more advanced

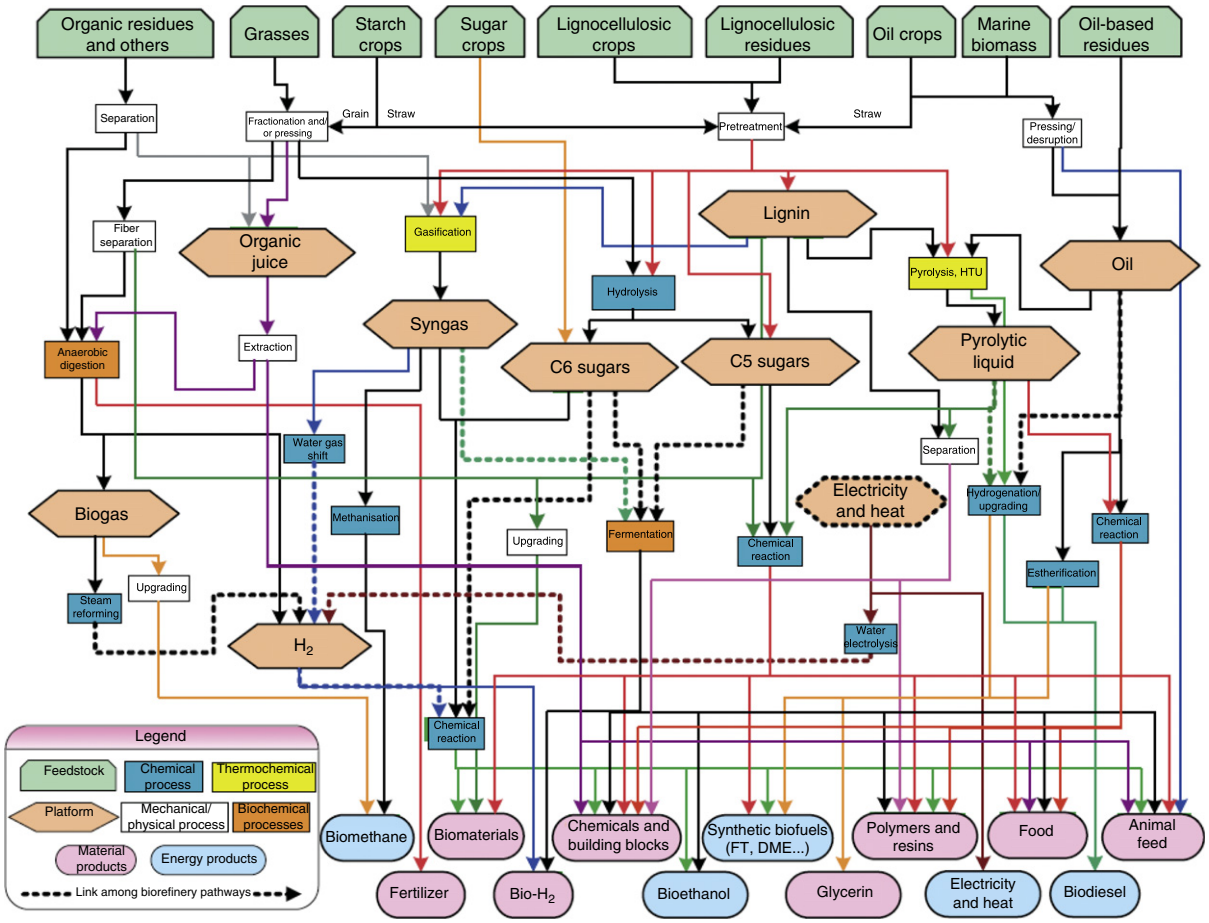

Figure 15 Partial classification system for biorefining options (Cherubini *et al.*, 2009).

production and processing and improved lifecycle performance. Third-generation biofuels are based on feedstocks modified to improve processing, such as reduced lignin or increased oil content. Fourth-generation technologies involve both improved feedstocks and improved processing and conversion techniques, including genetically modified microorganisms, that result in net negative carbon impacts as an outcome of the biofuel production system (Lu *et al.*, 2011).

The conversion strategies are integrally coupled to the properties of the biomass. Moisture has often been used as a discriminating parameter in the selection between thermochemical and biochemical processes, although by itself this is not usually sufficient. In many cases, the properties of the biomass necessary for engineering design have not been properly characterized before commercial implementation of a technology. Operation of combustion-type power-generating stations intended to burn certain types of agricultural residues (in particular cereal straws and other herbaceous biomass) has been hindered by fouling of boiler heat transfer surfaces from the inorganic compounds in the biomass (Turnbull, 1991; Wiltsee, 2000; Jenkins *et al.*, 1998, 2011), a phenomenon that was largely overlooked in the design phase of many facilities, but is well known for coal (Baxter, 1992). Effective biomass energy development demands a continuing program in resource and technology development.

Thermochemical Conversion

Combustion

Historically, and still so today, the most widely applied energy conversion method for biomass is combustion. The chemical energy of the fuel is converted into heat energy. Heat can be used directly and also transformed by heat engines of all sorts into mechanical and electrical energy. Theoretically, biomass could be directly converted into electricity by magnetohydrodynamic power generation in the same way coal might be, but the technology is still mostly speculative (Rosa, 1961; Mikheev *et al.*, 2006). Burning of wood and agricultural materials in open fires and simple stoves for cooking and space heating is common around the world and a vital source of heat, although less desirable than advanced conversion techniques from the perspective of atmospheric pollution and undue health impacts from incomplete combustion (Jenkins *et al.*, 2011). Electricity generation using biomass fuels has received considerable attention in recent years, although sugarcane bagasse has long been used as fuel for electricity generation at sugar mills and is now an integral component of biofuel production from sugarcane with surplus power exported for distribution. Wood also has been widely used for cogeneration of heat and electricity in sawmills, with heat and steam generation being the primary function for kiln drying of lumber.

A large independent power-generation industry in the US developed in response to incentives provided directly and indirectly by federal legislation, with approximately 10 GW_e of electrical-generating capacity from biomass currently operating in the United States alone (EIA, 2013b). CHP facilities using wood, straw, and municipal solid wastes are operating in Europe and elsewhere for electricity generation and district heating (COGEN Europe, 2011). Additional incentives exist in the form of renewable portfolio standards (RPS) such as that in California that now calls for a third of retail electricity sales to come from renewable resources by the year 2020. Total installed capacity in biomass power generation around the world is approaching 50 000 MW_e including large-scale solid fuel combustion as well as small-scale digester and landfill gas applications (IEA, 2007). In many regions of the world, Asia being an exception, biomass utilization is below the sustainable resource capacity and potential exists to increase uses for fuels, heat, and power (Parikka, 2004).

Viewed simply, the complete combustion of biomass in air transforms the organic fraction into carbon dioxide and water:

$$C_xH_yO_z + n_1H_2O + n_2(1+e)(O_2 + 3.76N_2) = n_3CO_2 + n_4H_2O + n_5N_2 + n_6O_2 \quad [4]$$

where the stoichiometric coefficients n depend on the concentrations of carbon, hydrogen, and oxygen in the original feedstock (here expressed on a moisture-free, ash-free basis), and on the amount of excess oxygen, e, added to the reaction. Feedstock moisture is accounted for in the reaction by the coefficient n_1, and air is approximated in the normal engineering fashion as consisting of 21% by volume oxygen and 79% equivalent nitrogen.

A more sophisticated global combustion reaction for biomass that better accounts for the range of species present is represented by the mass balance of eqn [5] in which the mass coefficients $m_{r,i}$ designate the masses of the reactant species and $m_{p,j}$ designate the product species. In this case, the biomass is divided into three fractions: an organic phase, a moisture phase, and an ash phase. The feedstock elemental mass fractions described by the coefficients γ_i arise from the analysis of the dry feedstock for C, H, O, N, S, and Cl. Moisture in biomass is represented by a separate water fraction (free and bound moisture). The oxidation medium, air, for example, is considered to consist of O_2, CO_2, H_2O, and N_2, all in the gas phase. The reaction is represented as resulting in eleven main gas phase products and a residual mass containing ash and unreacted portions of the other element masses from the biomass. The residual can consist of solids such as particulate matter, carbon in ash as charcoal or carbonates, and chlorides and sulfates in furnace deposits. Equation [5] is reasonably general in that it can equally be used to describe the combustion of other fuels such as (bio)methane, biodiesel, Fischer–Tropsch liquids, and other hydrocarbons, biooils from pyrolysis, and many others:

$$m_{r,1}\left(\sum_i \gamma_i \middle| C,H,O,N,S,Cl,ash\right) + m_{r,2}H_2O(l) + \ldots + m_{r,3}O_2 + m_{r,4}CO_2 + m_{r,5}H_2O(g) + m_{r,6}N_2 = \ldots = m_{p,1}CH_4 + m_{p,2}CO + m_{p,3}CO_2 + m_{p,4}H_2 + m_{p,5}H_2O + m_{p,6}HCl + \ldots \quad \ldots + m_{p,7}N_2 + m_{p,8}NO + m_{p,9}NO_2 + m_{p,10}O_2 + m_{p,11}SO_2 + m_{residual} \quad [5]$$

In addition to the product composition, eqn [5] allows for the estimation of other properties of the reaction, such as the flame temperature under different burning conditions, an important parameter for estimating heat transfer, efficiency, and thermal performance.

Equation [5] also specifies the oxidant-to-fuel ratio, or in the case of air as the source of oxygen, the air–fuel ratio, along with the equivalence ratios often used to specify combustion conditions. The air–fuel ratio, AF, defines the mass of air added relative to the mass of feedstock, expressed on either a wet or dry basis. The stoichiometric value, AF_s, defines the special case in which only the amount of air theoretically needed to completely burn the feedstock is added to the reaction. The air–fuel ratio, the fuel–air equivalence ratio, ϕ, the air–fuel equivalence ratio or air-factor, λ, and the excess air, e, are all related as follows:

$$\phi = \frac{AF_s}{AF} \quad \lambda = \frac{1}{\phi} \quad e = \lambda - 1 \quad [6]$$

The combustion regimes are defined by the value of ϕ with $\phi = 1$ ($e = 0$) being the stoichiometric combustion, $\phi > 1$ the fuel-rich regime (insufficient air), and $\phi < 1$ the fuel-lean regime (excess air). The equivalence ratio is particularly important in characterizing the potential air pollutant emissions from a combustion system. For fuel-rich conditions, concentrations increase for products of incomplete combustion such as hydrocarbons, CO, and particulate matter. NO_x emissions may peak under slightly fuel-lean conditions due to high flame temperatures and reaction of nitrogen and oxygen in air (the so-called thermal NO_x). NO_x is also produced from nitrogen in the feedstock (fuel NO_x). Other pollutant species are also produced in varying amounts under all three combustion regimes but are not specifically included in eqn [5].

Fuel moisture is a limiting factor in biomass combustion. The autothermal limit for most biomass fuels is approximately 65% moisture content wet basis (mass of water per mass of moist fuel). Above this point, insufficient heat is liberated by combustion to satisfy the energy needs for evaporation and product heating. Practically, most combustors require a supplemental fuel, such as natural gas, when burning biomass in excess of 55% moisture wet basis. In the US, Federal Energy Regulatory Commission regulations developed after the enactment of the Public Utilities Regulatory Policies Act in 1978 permit up to 25% of the power plant energy input to come from natural gas or other fossil fuel (depending on air permits) for qualifying biomass cogenerators. Many independent power producers and biomass facilities employ cofiring for startup and flame stabilization.

The most common type of biomass-fueled power plant today utilizes the conventional Rankine or steam cycle, as illustrated in **Figure 16**. The fuel is burned in a boiler, which consists of a furnace and one or more heat exchangers to make superheated steam. Typical medium efficiency units utilize steam temperatures and pressures of approximately 500 °C and 6 MPa. The steam is expanded through one or more turbines that drive an electrical generator. The steam from the turbine exhaust is condensed, and the water recirculated to the boiler through the feedwater pumps. Combustion products exit the combustor, are cleaned, and vented to the atmosphere.

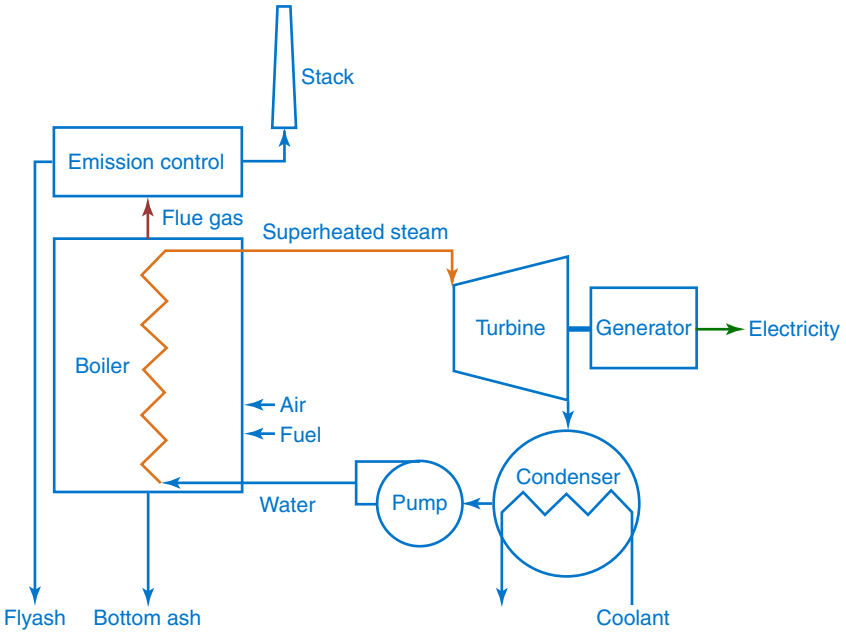

Figure 16 Schematic of a Rankine or steam cycle power plant.

Typical cleaning devices include wet or dry scrubbers for sulfur and chloride control, cyclones or other inertial separation devices, baghouses (filters) or electrostatic precipitators for particulate matter removal, and selective catalytic or selective noncatalytic reduction of NO_x. Low CO and hydrocarbon emissions are maintained primarily by proper control of air–fuel ratio in the furnace and boiler.

Ash fouling on the superheaters, the heat exchangers used to increase steam temperature above its saturation temperature and that are commonly located in the hottest parts of the furnace, has been a severe problem in many biomass-fueled boilers. Pretreatment of the feedstock to remove much of the alkali and chloride before firing to the boiler has proved beneficial in reducing fouling (Jenkins *et al.*, 1998, 2011). Coproduct bottom and fly ash can be used for industrial materials or land applied as fertilizers, potentially from the same fields that produced the feedstock. Ash from municipal solid waste incinerators, which commonly employ additional control of chlorides, mercury, and other hazardous products, may require hazardous waste disposal.

Individual power plants using biomass fuels in the manner described here typically range up to approximately 50 MW electrical capacity, which in the US is sufficient to supply the needs of from 25 000 to 50 000 people. Larger sizes are possible, and size selection is accomplished through an analysis of fuel resource availability, plant economy, and local regulations as described earlier under feedstock logistics. The distributed nature of biomass fuels and the limited economy of scale associated with plants of this type have kept the size of individual facilities relatively small in comparison with coal, petroleum, or nuclear-fueled power-generating stations. The largest biomass-fueled power station is a 240 MWe unit in Finland that operates at 545 °C and 16.5 MPa and produces process steam and hot water for district heating, but this unit can also accept peat and coal as fuel (Alholmens Kraft, 2013). A larger project in the UK (750 MWe) based on replacing coal with biomass was recently abandoned for financial and feedstock supply reasons, the latter based on uncertainties about local supplies from the region (Ross, 2013). Conversion of coal-fired facilities to biomass continues to be considered, however, in order to help meet the standards for reduced greenhouse gas emissions.

The efficiencies of biomass power plants are generally lower than comparable fossil-fueled units because of higher fuel moisture content, lower steam temperatures and pressures (due to the need to control fouling at higher combustion gas temperatures), and to some extent the smaller sizes, with a proportionately higher parasitic power demand for pumps, fans, and other electrical devices associated with the power plant itself. Large fossil-fueled units normally incur approximately 3% parasitic demand but with biomass plants the demand is more commonly approximately 10%. Currently, biomass power plant efficiencies are in the range of 17–28%, compared with good single-cycle fossil-fueled units ranging up to 40% overall efficiency. Gas and distillate (diesel) fired combined cycle power plants have efficiencies ranging more than 50% overall. Biomass integrated combined cycles are projected to exceed 35% electrical efficiency. Cofiring of biomass at 10–15% of energy input in higher capacity, higher efficiency fossil (e.g., coal) stations can also lead to a higher efficiency in biomass conversion. Increasing the power generation efficiency is a major goal for advanced biomass designs (Jenkins *et al.*, 2011).

Gasification and pyrolysis

On heating, biomass fuels will decompose into a number of gaseous and condensable species, leaving behind a solid carbonaceous residue known as char. This is an early stage of combustion, and the luminous flame seen when burning wood and other biomass is a result of the oxidation of volatile

compounds emitted during pyrolysis and gasification of the feedstock and thermal radiation from soot particles from the flame giving a characteristic yellow color.

When the fuel–air equivalence ratio, ϕ, of eqn [6] is substantially greater than unity (fuel-rich), the fuel will be only partially oxidized due to the insufficient oxygen, and the reaction products will consist not only of carbon dioxide and water, but of large amounts of carbon monoxide and hydrogen in addition to variable amounts of gaseous hydrocarbons and condensable compounds (tars and oils), along with char and ash. Other oxidants, including steam, can also be used instead of air, in which case the reaction product suite will differ. Reaction conditions can be varied to maximize the production of fuel gases, fuel liquids, or char (as for charcoal), depending on the intended energy market or markets. The term gasification is applied to processes that are optimized for fuel gas production (principally CO, H_2, and light hydrocarbons). Under heating alone without the addition of an oxidant the feedstock will pyrolyze. Pyrolysis reactors are typically designed to maximize the production of liquids through fast rather than slow heating although increasing interest in biochar or black carbon is now shifting the preferred product mix. Catalysts are sometimes employed to promote various reactions, especially the cracking of high molecular weight hydrocarbons produced during gasification and also in chemical catalytic synthesis of liquid hydrocarbons and other products in making transportation biofuels.

Gasification technology was developed more than 200 years ago (Kaupp and Goss, 1984), and lately has been improved primarily for the purposes of providing solid fuels (biomass, coal, and coke) access to some of the same commercial markets as natural gas and petroleum. Gasifiers have long been used to convert solid fuels into fuel gases for operating internal combustion engines, both spark ignited (gasoline) and compression ignited (diesels). They can also be used for external combustion devices, such as boilers and Stirling engines. The most common types are the direct gasifiers, where the partial oxidation of the feedstock in the fuel bed provides the heat for pyrolysis and gasification reactions, which are mostly endothermic. Indirect gasifiers and pyrolysis reactors use external heat transfer to provide the heat necessary to pyrolyze the fuel. The heat may be produced by the combustion of some of the original biomass fuel, or by the combustion of output fuel gases, liquids, or char. Allothermal reactors have been developed to supply heat by internal but separate burning of the char phase following gasification of the feedstock, mostly in dual reactor systems (Wilk and Hofbauer, 2013). Gasifiers may have less difficulty with ash slagging because of the lower operating temperatures compared with combustors, although slagging, fouling, and bed agglomeration remain problems with some fuels (e.g., straw).

When direct gasifiers are supplied with air to react the feedstock, the fuel gases will contain large amounts of nitrogen and the heating value or energy content of the gas will be low (3–6 MJ m^{-3}) in comparison to natural gas (compare methane at 36.1 MJ m^{-3}) and other more conventional fuels. Nonsupercharged engines operating on such gas will be derated in power output relative to their operation on gasoline or diesel (Jenkins and Goss, 1988). In the case of diesel engines, the gas cannot be used alone, and pilot amounts of diesel fuel are injected to provide proper ignition and timing. For spark-ignited engines, the engine power output is about half that of the same engine on gasoline, because the air capacity of the engine (the amount of air drawn into the engine cylinder during the intake stroke) is reduced by the large volume occupied by the fuel gas, and so not as much fuel can be burned during each cycle (Jenkins and Goss, 1988). Supercharging the engine can overcome this in part. For dual-fuel diesel engines, the gas can generally supply up to 70% of the total fuel energy without encountering severe knock, which results from the long ignition delay associated with the producer gas, the same property which gives the gas excellent octane rating (Chancellor, 1980; Ogunlowo *et al.*, 1981). The same properties of producer gas which lead to late ignition and knock in a diesel engine make it quite knock resistant in a spark-ignited engine, so compression ratios well above 10 can be used. With proper design of the cylinder head at increased compression ratio, the engine efficiency can be improved over gasoline, offsetting some of the derating due to reduced air capacity.

If the gasification reactor uses enriched or pure oxygen, the fuel gas, or syngas, produced is of higher quality. The cost of producing the oxygen is high, however, and such systems are generally proposed for larger scales or for producing higher value commodities, such as chemicals and liquid fuels. Methanol, a liquid alcohol fuel, CH_3OH, is produced by the catalytic reaction

$$CO + 2H_2 = CH_3OH \qquad [7]$$

This reaction is favored by low temperature (400 °C) but by high pressure (30–38 MPa). Zinc oxide and chromic oxide are the common catalysts. With copper as the catalyst, the reaction temperature and pressure can be reduced (260 °C, 5 MPa), but copper is sensitive to sulfur poisoning and requires good gas scrubbing (Probstein and Hicks, 1982). Fischer–Tropsch reactions can be utilized to produce a spectrum of chemicals including alcohols and aliphatic hydrocarbons. Temperature and pressure requirements are reduced, and greater selectivity can be obtained by the choice of catalyst.

Liquids, such as gasolines, can be produced via indirect routes involving the gasification or pyrolysis of the solid biomass to produce reactive intermediates that can be catalytically upgraded (Kuester *et al.*, 1985; Prasad and Kuester, 1988; Kuester, 1991; Brown, 2011). Liquids produced directly by pyrolysis are usually corrosive, suffer from oxidative instability, and cannot be directly used as engine fuels. Many products are also carcinogenic. Refining of some sort is generally necessary to produce marketable compounds. Despite this, fast pyrolysis reactors employing biomass and other fuels are in commercial startup to produce biooils (Ensyn Corp, 2014). Liquid fuels can also be produced by direct thermochemical routes, such as by hydrogenation in a solvent with a catalyst present (Elliott *et al.*, 1991; Bridgwater and Bridge, 1991).

One of the principal technical hurdles, especially at the small scale, in applying gasifiers for applications other than direct burning of the raw gas is gas cleaning and purification. Removal of particulate matter and tars from the gas is critical in downstream power generation and fuel synthesis. Tars comprise a class of heavy organic materials that are particularly difficult to remove or treat. Systems are available to produce acceptable gas quality, but generally rely on some

combination of wet and dry scrubbing and filtering and add expense to the conversion system. Small-scale gasifiers used for remote power generation have often been deployed without adequate handling procedures for tar separated from the gas. Gas cleaning and tar handling remain critical engineering challenges for a wider adoption of the technology at all scales.

Advanced power generation options from biomass include the use of a biomass gasifier to produce fuel gas for a gas turbine in an integrated gasification combined cycle system (**Figure 17**; Meerman *et al.*, 2013). The efficiency of these systems could be considerably higher than the conventional Rankine cycle power generation systems. Major engineering challenges include hot gas cleaning to provide a gas of adequate quality to avoid fouling the turbine, and the development of reliable high pressure reactors or compressors and fuel feeding systems. The use of a gasifier is thought to be an advantage over a direct combustor because heat loss in the gas cleaning system is of less concern, most of the fuel energy being in the form of chemical energy in the product gas. Other advantages for gasifiers over combustors include the ability to operate at lower temperatures, and lower gas volumes per unit of feedstock converted, which assists in the removal of sulfur and nitrogen compounds to reduce pollutant emissions. Systems of this type are currently under development and several large-scale demonstration projects have been completed, but the technology has not yet been deployed commercially for

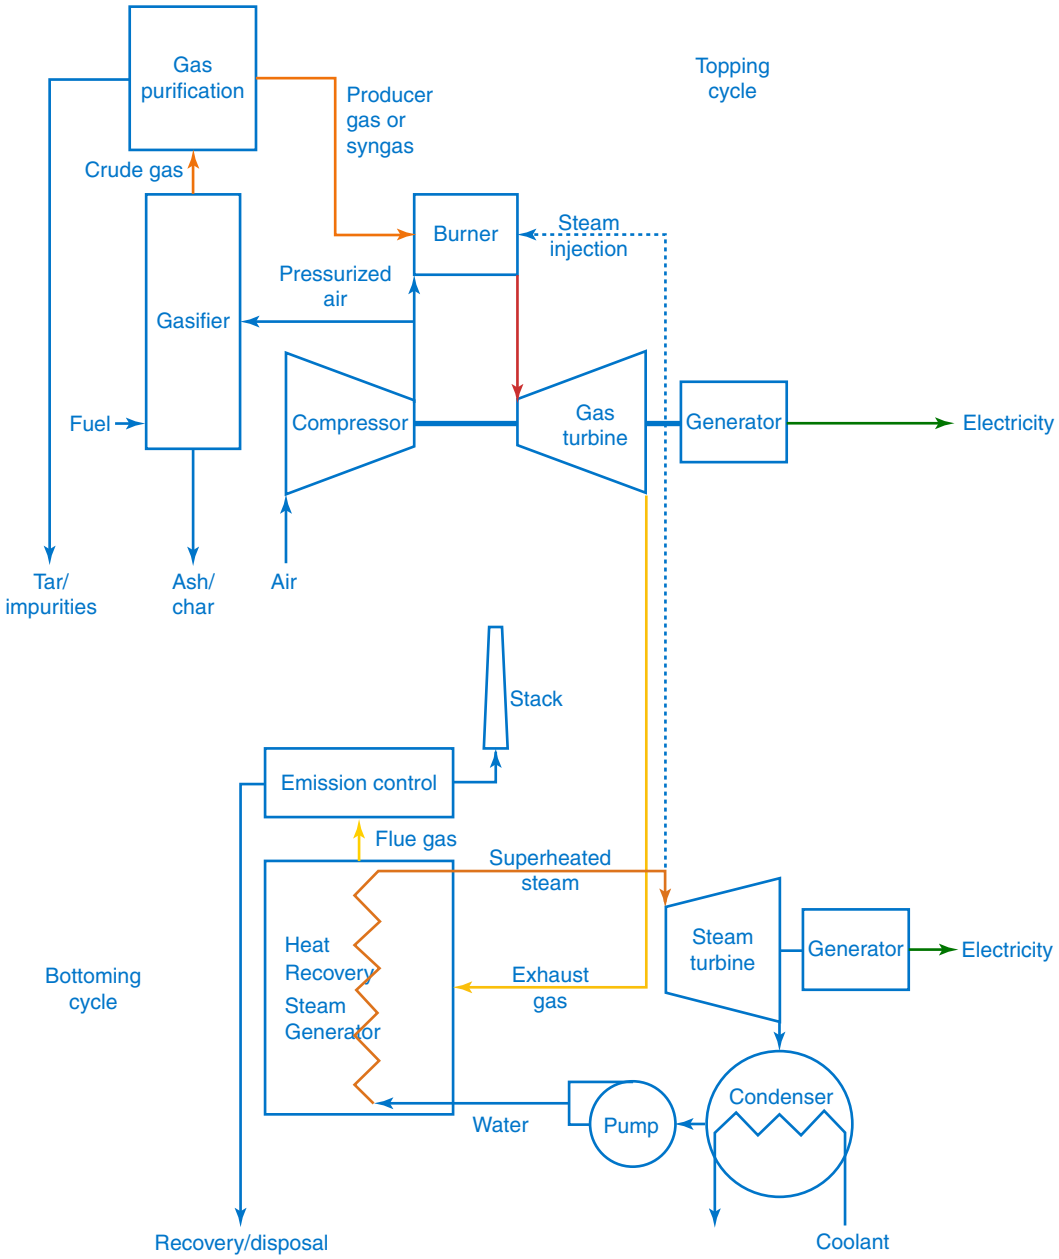

Figure 17 Integrated gasification combined cycle advanced power generation concept. Pressurized air gasification shown. A steam-injected gas turbine option is also shown (IG/STIG).

biomass although it has for coal at larger scales (Stahl and Neergaard, 1998). **Figure 17** also illustrates the possible use of steam injection for reducing thermal NO_x emissions and enhancing the power output of the gas turbine. The high heat capacity of the steam in comparison to the combustion products leads to a power increase, and the addition of steam reduces the flame temperature, which is beneficial for reducing thermal NO_x formation (Weston, 1992). Many other thermochemical conversion options are under development (Brown, 2011).

Biochemical Conversion

Biochemical conversion relies primarily on the abilities of microorganisms to convert biomass components into useful liquids and gases. Yeast fermentation is the principal means of producing ethanol. Biogas is a product of bacterial fermentation in anaerobic digestion, although bacteria are also used in alcohol fermentation. Fermentation is a widely used industrial process and an active area of biotechnology research and development.

Fermentation

Ethanol (C_2H_6O) is widely produced by fermentation and is the predominant liquid fuel derived by biochemical means from biomass. In the United States, ethanol is currently used as a oxygenate blending agent in gasoline to help reduce air pollutant emissions from vehicles as well as a major fuel product in the form of E85, an ethanol–gasoline blend containing nominally 85% ethanol and 15% gasoline although actual blends may range as low as 70% ethanol. In Brazil, ethanol is used both as a pure or 'neat' (100% ethanol) fuel, and as a blending agent with gasoline at 20% concentration (E20). The primary feedstock for ethanol production in the United States is corn (maize) grain as a source of readily fermentable starch but sorghum and other agricultural feedstocks are used as well. In Brazil it is sugarcane as a source of sugar. The yeast *Saccharomyces cerevisiae* has been the most widely used organism for ethanol fermentation (Sen, 1989). The fermentation process involves the necessary pretreatment of the feedstock to produce a fermentable substrate (sugar), fermentation, and product separation.

Corn biorefineries producing ethanol are of two types: wet mills and dry mills. Wet mills extract multiple products from the grain including oil, fiber, gluten, and starch, with the starch fraction used for fermentation. Dry mills (**Figure 18**) use the entire corn kernel for fermentation. The grain is not directly fermentable, but requires milling, hydration and gelatinization, and enzymatic or acid hydrolysis of the starch to fermentable sugars before the actual fermentation. Theoretical yields from glucose ($C_6H_{12}O_6$) are 51% ethanol and 49% carbon dioxide (mass basis). The overall reaction for the fermentation of glucose to ethanol is

$$C_6H_{12}O_6 = 2C_2H_6O + 2CO_2 \quad [8]$$

The theoretical yields from starch and sucrose are somewhat higher. Actual yields from fermentation are lower due to production of the microbial cell biomass and incomplete conversion of the substrate.

Ethanol concentrations reach approximately 10% in the fermentation beer before separation; higher concentrations inhibit the microbial activity. The ethanol is typically separated by steam distillation to 95% concentration, the azeotropic point at which water and ethanol evaporate to yield the same concentration in the vapor as in the liquid and no further separation by distillation is possible. The distilled product is dehydrated using solvents or other desiccants to produce anhydrous ethanol. A high protein stillage is produced and is used as animal feed (distillers grains). Beverage grade alcohol includes removal of fusel oils during distillation. For fuel grade alcohol, this step is usually eliminated.

Cellulosic feedstocks are more difficult to hydrolyze into monosaccharides for fermentation, thereby incurring more costly pretreatment. Current methods under development for cellulosic biomass hydrolysis and fermentation essentially fall into four categories: (1) concentrated acid hydrolysis (**Figure 19**), (2) dilute acid hydrolysis, (3) enzymatic hydrolysis (**Figure 20**), and (4) thermochemical conversion (gasification and pyrolysis) followed by fermentation of synthesis gases, a process that attempts to circumvent problems associated with hydrolysis (Skidmore *et al.*, 2013). Concentrated acid processes have long been used to produce ethanol from cellulosic materials, but for economic and environmental reasons in modern applications require substantial recovery and recycling of the acid, adding expense. Enzymatic hydrolysis is widely investigated in an effort to improve yields and reduce costs. Enzymatic processes developed following research during World War II to control deterioration of military clothing and equipment. This research identified the fungal organism *Trichoderma viride*, later renamed *Trichoderma reesei*, important to the development of cellulose enzymes (cellulase) for decrystallization and hydrolysis of cellulose. Genetically modified and recombinant organisms have been developed to enhance both the hydrolysis and fermentation of cellulosic materials (Luli *et al.*, 2008; Singh, 2010). The cost of enzyme production remains high, however, and major research investigations continue to explore means of reducing the cost. Alternative techniques are under development to produce sugar aldonates as the reactive intermediates rather than sugars to replace the pretreatment, cellulase production, and enzymatic hydrolysis processes with a single biological step (Fan *et al.*, 2012).

Cellulose hydrolysis yields hexoses, primarily glucose, fructose, mannose, and galactose. Hemicellulose hydrolysis yields mostly pentoses, principally xylose and arabinose. Lignin is currently unfermentable in any commercial application. The sugars are fermented to ethanol whereas lignin is mostly considered as boiler fuel (e.g., in steam production for distillation and power generation) or for conversion to other products, such as aryl ethers (Salanitro, 1995; Sergeev and Hartwig, 2011; Parthasarathi *et al.*, 2011). Sequestering of lignin has also been proposed to reduce net greenhouse gas emissions from biochemical conversion (Murphy, 2013).

Energy balances associated with fermentation of lignocellulosic materials are thought to be improved relative to those for corn grain, although commercial data are not yet substantially available. For lignocellulosic feedstocks, overall ethanol yields are likely to be in the range of 300 l Mg^{-1} of dry feedstock compared with 400 l Mg^{-1} for corn grain. The ideal

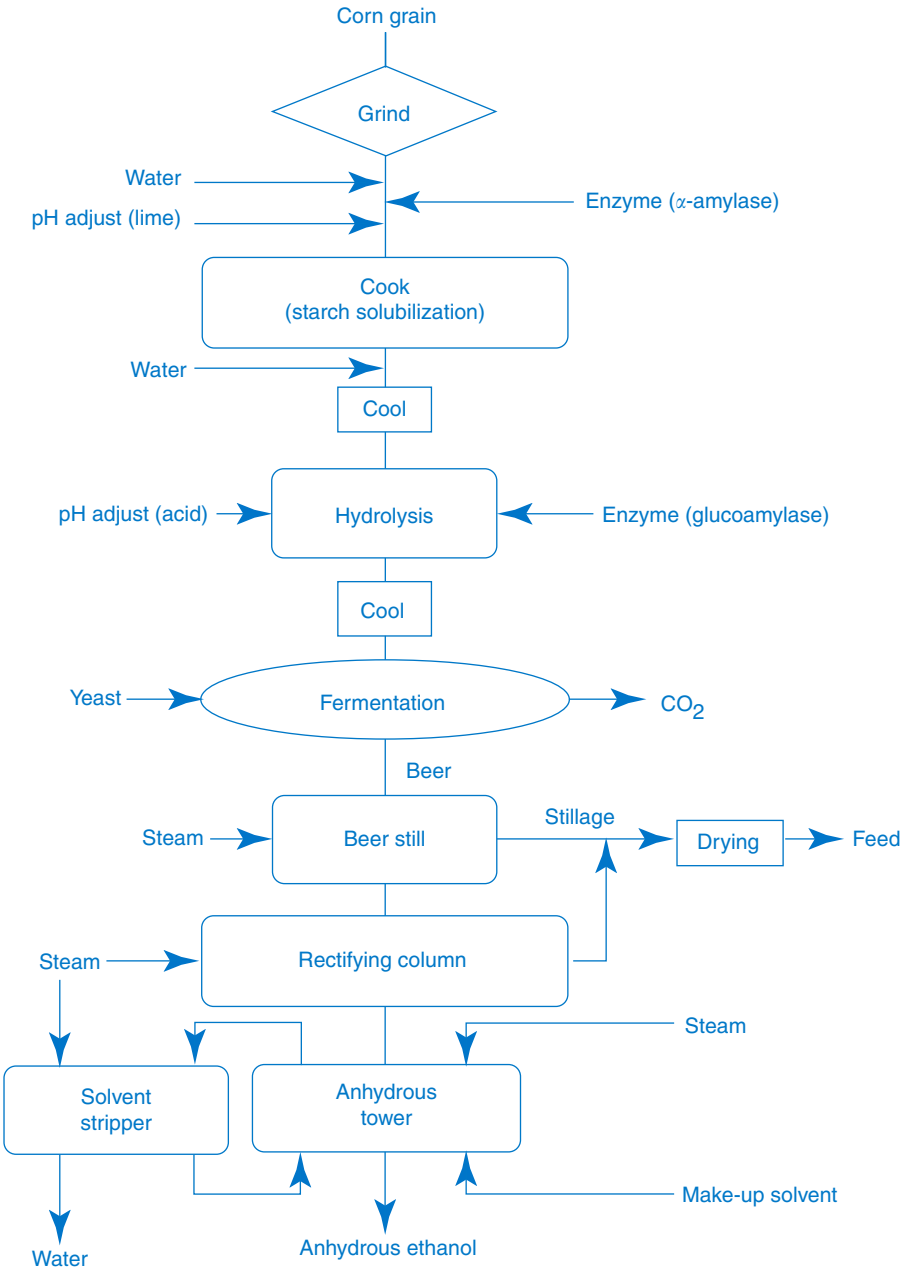

Figure 18 Process for the production of anhydrous ethanol from corn.

energy recovery assuming complete conversion into ethanol for cellulose fermentation is approximately 97% of the feedstock energy. The overall reaction of cellulose to glucose is

$$(C_6H_{10}O_5)_n + nH_2O = n(C_6H_{12}O_6) \quad [9]$$

with glucose fermented to ethanol as in reaction [8]. The fractional energy yield for cellulose to ethanol is shown in Table 6. Actual energy yields are substantially lower. At 300 l Mg^{-1} the energy yield from feedstock is 40%. This does not include the supplemental energy involved in feedstock production, handling, and conversion.

As an improvement over the separate hydrolysis and fermentation (SHF) of the cellulosic biomass, simultaneous saccharification and fermentation (SSF) processes are perceived to have certain advantages in avoiding end-point inhibition in the fermentation stage and the possibility of reducing the fermentation time. The cost of ethanol from SSF processes may, therefore, be reduced relative to SHF. In SSF, a mixed culture of organisms is used, typically *Brettanomyces claussenii* and *S. cerevisiae*, with *B. clausenii* being active early and the more robust *S. cerevisiae* continuing to completion. More recent developments employ simultaneous saccharification and cofermentation of multiple sugars, or combined enzyme production, saccharification, and fermentation

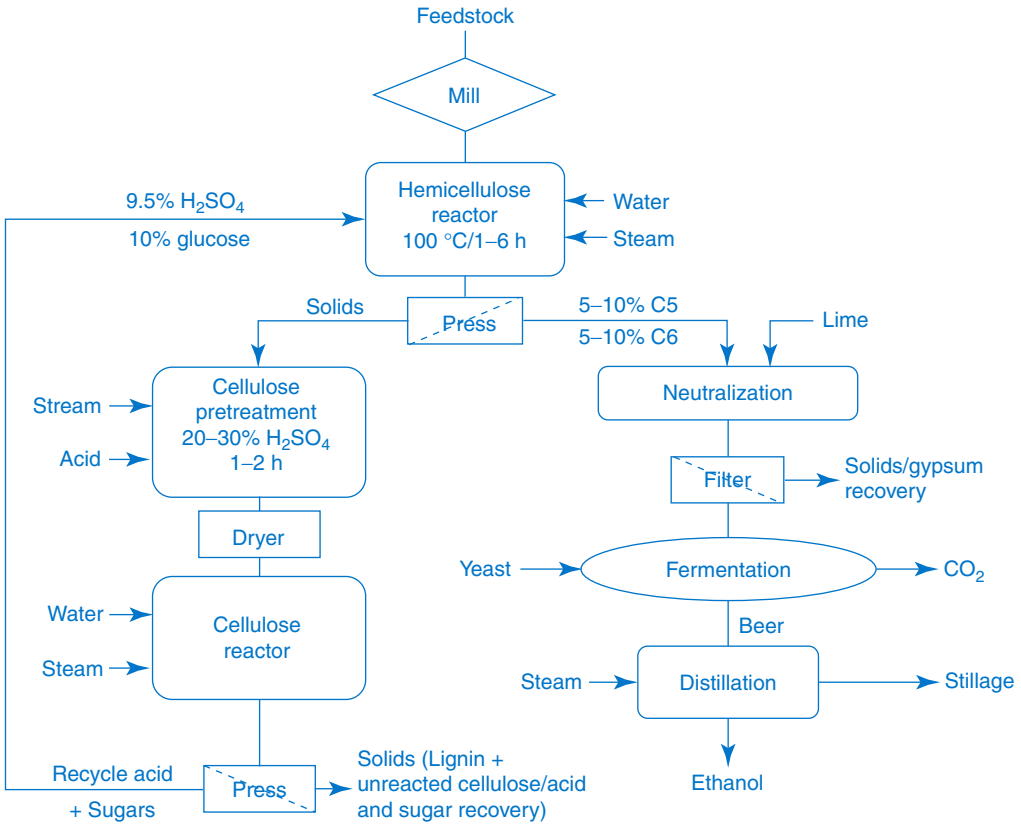

Figure 19 Process for fermenting cellulosic feedstocks using concentrated acid hydrolysis with acid recycle. Adapted from Barrier, J.W., Moore, M.R., Broder, J.D., 1986. Integrated Production of Ethanol and Coproducts from Agricultural Biomass. Muscle Shoals, AL: Tennessee Valley Authority.

processing in consolidated bioprocessing (Olson *et al.*, 2012).

Gasification systems coupled with a bioconversion stage are proposed to take advantage of the capability of anaerobic organisms, such as *Clostridium ljungdahlii* to ferment syngas to ethanol. These systems potentially would operate at a higher rate than the hydrolytic fermentation systems (Skidmore *et al.*, 2013).

Thirty-five percent of the weight of ethanol is due to oxygen. In the United States, ethanol is used as an oxygen source in gasolines where it assists in controlling CO emissions from engines. At present, ethanol can be blended up to 10% by volume. Fuel oxygen promotes CO oxidation to CO_2, and the ethanol in the gasoline tends to create a leaning effect in most spark-ignited engines, causing them to operate at higher effective air–fuel ratios with lower CO emission rates (OTA, 1990). Ethanol has a high octane rating, as does methanol, and engines using neat or blended fuels can be designed for higher compression ratios and higher efficiencies. Therefore, even though ethanol has a heating value which is 60% that of gasoline (**Table 7**), the effective fuel consumption on a properly configured engine should only be increased by approximately 25% relative to gasoline. Stable blends of ethanol with gasoline require anhydrous ethanol to avoid phase separation, an issue in ethanol transportation and distribution.

The use of ethanol as blending stock for gasoline in California has also been controversial due to the higher vapor pressures when blended compared with gasoline alone, although the vapor pressure of neat ethanol is less than gasoline. The higher blend vapor pressure can result in higher evaporative losses of reactive hydrocarbons, although improved automotive fuel systems have reduced this concern in late model vehicles and blending ratios have shifted from 5.7% to 10%. The hydrocarbons react with NO_x in the atmosphere to produce ozone, a lung irritant and undesirable tropospheric pollutant. The level of ethanol blending is also a point of contention between oil refiners and ethanol producers due to rules under the US federal renewable fuel standard (RFS), a part of the Energy Independence and Security Act of 2007 (U.S. Congress, 2007; Podkul, 2013). A 10% blend ratio limits the total amount of ethanol that can be used in motor fuel (the so-called blend wall), and changes in gasoline demand could result in refiner demands that are lower than called for under the RFS, making financing difficult for new biorefining capacity additions. Vehicle warranties, other than for E85-capable vehicles, mostly cover only up to 10% ethanol, adding to the blend-wall constraints. Further constraints to the growth of a corn ethanol industry in the United States and elsewhere arise in California from estimates of lifecycle carbon intensities (net greenhouse gas emissions) under the low-carbon fuel standard (LCFS) that requires fuel suppliers to reduce intensity by 10% (CARB, 2012). Where coal is used for process energy in biorefineries producing fuel ethanol, estimated carbon intensities exceed those of the reference gasoline from petroleum.

Table 6 Ideal fractional energy yields in the conversion of cellulose into ethanol (actual yields lower)

Compound	*Molecular weight (kg kmol^{-1})*	*Higher heating value (MJ kg^{-1})*	*Molar energy (MJ)*	*Fractional energy yield*
Cellulose	162	17.53	2840	1.000
Glucose	180	15.67	2820	0.993
Ethanol[a]	46	29.78	2740	0.965

[a]2 mol of ethanol produced per mole cellulose reacted.

Although concerns such as these will likely be resolved over the longer term, the role of policy is evident in influencing system design and industrial capacity.

Anaerobic digestion

Fermentation by anaerobic bacteria is used to produce biogas, a gaseous fuel consisting of 50–80% by volume methane, 15–45% carbon dioxide, and 5% water, with small concentrations of H_2S and other species (Krich *et al.*, 2005). The technology is extensively employed in municipal waste water treatment. Often the biogas is burned in engines to generate power, with engine waste heat used to heat the digester for improved performance. The same biological processes are active in waste landfills, where gas recovery has become an integral part of landfill design, both as a means to control gas migration and as a means of energy recovery. Other products can also be produced through anaerobic digestion including carboxylic acids, ketones, and alcohols (Thanakoses *et al.*, 2003).

Table 7 Properties of ethanol and gasoline

Property	*Ethanol*	*Unleaded regular gasoline*
Specific gravity (15 °C)	0.79	0.78
Lower heating value (MJ kg^{-1})	26.9	44.0
Lower heating value (MJ L^{-1})	21.2	34.3
Octane number ((R + M)/2)[a]	98	88
Stoichiometric air–fuel ratio	9.0	14.7
Lower heating value of stoichiometric air–fuel mixture (MJ kg^{-1})	2.7	2.8
Enthalpy of vaporization (kJ kg^{-1} at 15 °C)	840	335
Reid vapor pressure (kPa)[b]	16	55–103

[a]Average of research (R) and motor (M) octane test methods (pump value).
[b]Reid vapor pressure of 10% ethanol in gasoline is 3–7 kPa higher than gasoline alone.

The overall reaction for anaerobic digestion of the organic portion of the feedstock (represented as $C_xH_yO_z$) to biogas is

$$C_xH_yO_z + \left(x - \frac{y}{4} - \frac{z}{2}\right)H_2O = \left(\frac{x}{2} - \frac{y}{8} + \frac{z}{4}\right)CO_2 + \left(\frac{x}{2} + \frac{y}{8} - \frac{z}{4}\right)CH_4 \quad (10)$$

The actual concentration of CO_2 is typically reduced due to its solubility in water.

The digestion of the feedstock is commonly described as occurring in three stages although the cooperative mechanisms among the organisms involved has been emphasized (McInerney and Bryant, 1981; Hills and Roberts, 1982; Parkin and Owen, 1986). After loading feedstock to the digester vessel, much of the organic material is solubilized by bacterial metabolism or chemical hydrolysis. Acid-forming bacteria utilize the soluble compounds and produce low molecular weight organic acids, principally acetic acid, that are used by methanogenic (methane-forming) bacteria for the final conversion to biogas. In a properly operating digester, these processes take place simultaneously within the digester contents, although in some recent designs the hydrolysis and methanogenic processes have been largely separated (Zhang and Zhang, 1999). Acid-forming bacteria are generally more robust than the methanogens, and can overwhelm the system with acids, causing a decrease in pH and unfavorable conditions for the methanogens. A properly functioning digester will have a pH in the range of 7–8. The health of the digester is controlled by proper management of nutrient loading, retention time, temperature, and, in dilute slurry digesters, mixing.

Digesters most often operate with dilute slurries. Bioreactor designs include covered lagoons commonly used in dairy and other agricultural operations, batch digesters, plug-flow digesters, completely stirred tank reactors, upflow anaerobic sludge blanket systems, anaerobic sequencing batch reactor systems, anaerobic-phased solids systems, and in landfills enhanced bioreactors employing leachate recycle. Plug-flow reactors utilizing higher solids concentrations are also used. High solids or dry-fermentation digesters have been developed to reduce some of the problems associated with handling dilute slurries in tank reactors (Jewell, 1982). These high solids digesters are similar in nature to landfills, but implemented at smaller scales and with greater automation.

Digesters can operate on almost all biomass feedstocks, although with differing conversion rates and efficiencies. They are well suited for wet or moist feedstocks that would require drying for thermal conversion systems. Nitrogen availability is limiting in most cases, particularly when woods or herbaceous materials are used alone. Animal manures and mixtures of manures with agricultural residues, such as straw, give better performance due to improved carbon-to-nitrogen (C/N) ratios, which are recommended to be in the range of 25–30 overall (Hills and Roberts, 1981). The biogas produced typically has a heating value of 22–24 MJ m^{-3} with yields of 50–400 l per kg dry solids depending on feedstock and digester conditions, including temperature, inoculation levels, and hydraulic retention time. Design operating conditions include the psychrophilic (ambient temperature or below), mesophilic (30–40 °C), and thermophilic temperature regimes (50–60 °C) with conversion rates generally increasing with temperature although heating requirements also increase. Hyperthermophiles that can withstand even higher temperatures have not yet been employed in commercial systems. Energy conversion efficiencies for anaerobic digesters are relatively low if based on the yield of the gas alone. Typical energy efficiencies of biogas are 20–50%, and up to approximately 20% for electricity. The stabilized sludge remaining after digestion can be used as fertilizer, unless contaminated with heavy metals or other toxic materials from the input feed. Nutrient management is an important issue in many agricultural systems and digesters can be used to advantage, especially in mineralizing nitrogen before land application or discharge of effluent.

Biogas is a reasonably versatile fuel and can be burned directly for heating the digester (to improve performance), to heat water, or for cooking and lighting purposes. The gas can also be used as fuel for engines, turbines, and boilers, including cogeneration, and more recently in fuel cells (Krich *et al.*, 2005; Lo Faro *et al.*, 2013). As noted earlier, NO_x emissions from engines are currently a key issue for small digester-power systems. H_2S can be scrubbed from the gas to reduce corrosion and SO_2 emissions, although in small-scale applications such as individual dairy operations, the cost of more effective removal systems is a concern. Siloxanes typically present in landfill gas may need scrubbing (usually on charcoal) for some applications, turbines in particular and also in fuel cells and reciprocating engines. Biogas has been used as transportation fuel, including low pressure applications with large flexible bags on the roof of the vehicle serving as the fuel tank (Stout, 1990), but is now more widely considered for CNG or LNG applications. CO_2 stripping followed by gas compression is mostly required for these purposes. CO_2 stripping has also been used to produce pipeline quality gas for blending into natural gas distribution systems and to produce transportation fuels. Small-scale digesters have been promoted in many areas to improve sanitation as well as to supply fuel gas. The process is also considered in the design of integrated biorefineries (Thomsen *et al.*, 2013).

Physicochemical Conversion

Biodiesel has recently emerged as a commercial renewable alternative to petroleum-derived diesel. Biodiesel can be produced from virgin plant and algal oils and also from waste oils such as cooking oils and greases, the latter incurring lower procurement costs and hence lower cost of production. In the United States, the RFS mandates increasing the amounts of biodiesel although the amount required is a fairly small share of the total biofuel under the standard (U.S. Congress, 2007). Recent reversals in European Union (EU) policies due to sustainability concerns have reduced mandated biofuel volumes with impacts on the existing biodiesel producers and suppliers. Although potentially resource and policy constrained, the current production of biodiesel represents one of the predominant physicochemical conversion techniques.

Unlike petroleum-based diesel fuels, which are primarily straight or branched chain hydrocarbons, vegetable oils are primarily mixtures of triacylglycerols composed of fatty acids esterified to the three –OH positions on glycerol (Goering

et al., 1982; Robbelen *et al.*, 1989). Although crude or refined vegetable oils can be used as fuel for compression-ignited (diesel) engines, such use is not recommended except on an emergency basis for short periods of time (Peterson, 1989). Engine damage arising from fuel polymerization and ring sticking, along with lubricating oil contamination, is likely to occur after prolonged operation. Vegetable oils have heating values similar to diesel fuel (approximately 90% of ASTM No. 2 diesel), but the viscosity is one to two orders of magnitude higher. The high viscosity causes irregular spray patterns from fuel injectors inside the engine cylinders, which in turn leads to injector coking (carbonization of the fuel on the injector nozzles) and deposits on cylinder walls and pistons. Vegetable oils also have higher cloud point and pour point temperatures, which makes them inferior to diesel fuels for cold weather operation. However, they have higher flash point temperatures, and are therefore somewhat safer, and are less toxic than diesel fuels and mostly biodegradable. Stable blends of diesel fuel with vegetable oils can be made to improve the fuel properties, but modification of the oil is preferred for general engine application.

The reaction of a triglyceride, such as a vegetable oil, with an alcohol in the presence of a catalyst such as sodium hydroxide, produces upon separation a fatty acid ester and glycerol. The ester is an improved diesel fuel substitute over the original oil and the basis for current biodiesel manufacturing. When methanol is used, the result is a fatty acid methyl ester. Fatty acid ethyl esters, produced from oil and ethanol, have also emerged as diesel fuel replacements, with some possible advantages over the methyl esters in reduced smoke opacity and lower injector coking. The esters have viscosities that are only 2–3 times that of diesel fuel, which leads to reduced injector coking and decreased deposit formation compared with the original vegetable oil. The esters have improved cetane numbers relative to the original oils, and in some cases relative to diesel fuel. This makes them useful as blending stocks for diesel. Although esters reduce smoke emissions compared with diesel fuel, NO_x emissions are about the same or higher, as are acrolein emissions. Aromatic aldehyde emissions depend on the aromaticity of the fuel such that blends of biodiesel with regular diesel tend to have higher emissions than pure biodiesel fuel (B100) (Qi *et al.*, 2013; Cahill and Okamoto, 2012).

Fuel specification standards for biodiesel have been developed in Europe (Mittelbach *et al.*, 1992) and the US including standards (ASTM D6751, 2012) for 100% biodiesel fuel (B100) as blending stock for distillate fuels. Owing to its typically low sulfur content, biodiesel can be blended with petroleum diesel that otherwise does not meet newer low-sulfur fuel standards. B20, a 20% biodiesel blend, can be used in some unmodified diesel engines. The use of B100 may require modifications to the fuel supply system if the engine has not been warranted for it.

The Challenge of Sustainability

The production of industrial feedstocks by agriculture involves land and other resources that provide many different agronomic and ecosystem services. As the scale of production capacity for fuels and other commodity chemicals has increased, so has the debate around the wisdom of converting forest lands and prime or marginal agricultural lands to purposes other than traditional food, feed, and fiber production, especially food for a growing global population. Policies intended to improve sustainability in one sector, such as energy security, have often been contested for their narrow focus and lack of analysis and consideration of larger system issues, such as net global greenhouse gas emissions or net energy benefits (Searchinger, 2008; Pimentel, 1991). The reversal in EU policies regarding biofuels was motivated largely by reconsideration of sustainability impacts associated with resourcing large supplies of biodiesel and other fuels from palm oil and other crops where global environmental, social, and economic impacts had not been systematically evaluated (Turner *et al.*, 2008).

Challenges to US federal policies relating to biofuels developed following the first oil shock of 1973–74 when the US initiated policy supporting alternative fuels. Debate initially centered on net energy yields associated with producing ethanol from corn with suggestions that the amount of energy embodied in fossil fuels and other inputs to grow corn and manufacture ethanol exceeded the energy in the ethanol, thus negating any intended energy benefits (Pimentel, 1991). Criticisms were largely addressed through improvements in conversion technologies (Shapouri *et al.*, 2002; Farrell *et al.*, 2006), but other questions of sustainability continue to arise. In addition to a more recent debate over the net greenhouse gas emissions from industrial feedstock production, the effects on food prices have been called into question (the food-versus-fuel debate) with concerns over food security, especially for the poor. The Brazilian program to produce ethanol from sugarcane, widely viewed as a successful national response to improve domestic energy security, also generates concerns over environmental sustainability although the net greenhouse gas impacts are mostly regarded as lower than for corn (Smeets *et al.*, 2008).

The global energy markets are large and can easily absorb large quantities of feedstock biomass. Estimates for the United States suggest that only approximately a third or less of transportation fuel could be supplied from biomass (Perlack and Stokes, 2011; Parker *et al.*, 2011). Increasing biofuel demand potentially leads to direct land-use changes (dLUCs) as well as indirect land-use changes (iLUCs) through market-mediated effects (Searchinger *et al.*, 2008) unless yield intensification on the same land base is able to compensate, a goal of crop research but not so far achieved. iLUC can cause substantial emissions of carbon to the atmosphere from clearing of standing biomass and depletion of carbon stocks in the soil in response to crop shifting elsewhere in the world (Fargione *et al.*, 2008; Searchinger *et al.*, 2008). The amount of carbon released, like many other issues in agricultural sustainability, is highly uncertain and estimates vary widely. Inclusion of iLUC effects in environmental lifecycle assessments can result in higher attributed greenhouse gas emissions for some biofuels in comparison with petroleum-derived gasoline or diesel fuels. Policies to encourage biofuels based solely on direct substitution effects therefore may fail to achieve the intended outcomes for total greenhouse gas emission reductions. In California, the development of a LCFS to limit the

carbon intensity of transport fuels and electricity so as to reduce carbon emissions has been particularly contentious (CARB, 2012). Other standards, such as the US renewable fuel standard (U.S. Congress, 2007), also require set levels of lifecycle greenhouse gas emission reductions to qualify for a renewable identification number for the fuel, a key objective for market access and financial success in meeting fuel blending obligations (U.S. Congress, 2005; 2007). Sustainability considerations for biofuels also apply to issues of environmental justice and other social implications in addition to environmental and economic effects (RSB, 2010).

Bioenergy production has been viewed as a way to provide additional economic opportunities for farms and rural areas, improve the environment, enhance energy security, and help to stabilize fuel prices. Substitution of biofuels for gasoline and other petroleum products can result in direct reductions in greenhouse gas emissions and other benefits, but can also lead to changes in the type of air pollutants that are emitted, affect water demand and quality, alter land use, and increase or destabilize other commodity prices. Demand for wood and other biomass feedstocks for traditional uses in cooking, heating, and charcoal making has contributed to deforestation in many regions of the world in addition to causing adverse health effects from exposure to smoke (Jenkins *et al.*, 2011). Concerns have long been expressed over harvesting of agricultural residues for energy and other industrial uses due to possible agronomic impacts associated with nutrient depletion, changes to soil organic matter and carbon, and soil erosion (Jenkins *et al.*, 1981). Similar criticisms arise in the large-scale production of chemicals and materials from agriculture. In adopting new uses for crops and resources, careful consideration must be given to the lifecycle impacts and sustainability of the entire production system and feedstock supply chain.

Economic sustainability is a primary factor in motivating investment financing for industrial feedstock production, where environmental and social sustainability factors are satisfied. The costs of producing energy and other products from biomass are heavily influenced by feedstock acquisition costs as well as by the costs of conversion. For comparison, costs to generate electricity in the existing biomass-fueled power plants are approximately US$0.06–0.08 kWh^{-1} (US$17–22 per GJ), sometimes higher, at an average fuel cost of US$30 per metric ton, principally as wood residue (Jenkins, 2005). Cost projections for purpose-grown crops range substantially higher, typically beyond $50 per metric ton dry weight and often more than $100 per metric ton (Parker *et al.*, 2011).

Exclusive of harvesting and downstream processing and conversion operations, production costs for agricultural and other biomass residues are typically allocated to the primary crop production system and not always separately accounted. Byproduct or waste biomass may be available at no cost, or in some cases disposal fees (tipping fees) can be applied to cover the costs of handling, an advantage to systems receiving municipal solid wastes. In contrast, industrial and energy crops assume full allocation of production costs. These costs are quite variable depending on the species, production site, level of management, and resulting yield. Total average delivered costs, including harvesting and transportation (85 km), for *Eucalyptus* plantations in northeast Brazil producing at 12.5 Mg ha^{-1} $year^{-1}$ have been estimated at US$2.50–3.40 per GJ, or approximately US$52–67 per metric ton dry matter (CPI inflation adjusted 2013 US dollars) (Hall *et al.*, 1993). Of the total, 40% is associated with stand establishment including nursery production, land, planting, and administration, and another 10% is associated with plantation maintenance including management, cultivation, and research. Half the delivered cost is in the production of the biomass. Under Canadian conditions, the total delivered cost including harvesting, chipping, and transportation for a typical 5 year rotation, 4 rotation cycle forestry crop with a yield of 12 Mg ha^{-1} $year^{-1}$, was similarly estimated at US$58 per metric ton (CPI adjusted 2013 US dollars), of which 40% was allocated to the production system including land, nursery, planting, and tending (Golob, 1987).

Other energy and chemical feedstock costs influence decisions to produce industrial feedstocks from agriculture. Natural gas prices in the US in the period 1999–2001, for example, fluctuated between US$2 and US$15 per GJ. Owing to the development of hydraulic fracturing (fracking) techniques and expansion of natural gas reserves, prices are now in the vicinity of US$3 per GJ and anticipated to remain below US$4 per GJ through 2020, increasing to US$8 per GJ by 2040 (EIA, 2013c). Although policies such as California's RPS require increasing supplies of electricity from renewable sources, resource neutrality within the policy provides no specific advantage for biomass over other renewable resources and principal capacity additions have been in wind and solar (EIA, 2013d). Policy stability is also important in motivating financing for biorefineries and other industrial applications. Reversals such as that of the EU over biofuels (colloquially referred to as the 'biofuels disaster') and possible adjustments in the renewable fuel obligations under the RFS in the US create significant uncertainties associated with security of investments in facilities with decades-long economic lifetimes. Research along with genetic and cultural improvements are projected to reduce biomass production costs, but biomass production levels will also be influenced by direct and indirect environmental and socioeconomic consequences external to the direct costs of production (Hanegraaf *et al.*, 1998).

Sustainable large-scale production of industrial feedstocks will require a broad systems view and well-designed standards and best practices. International standards for certifying sustainable production of biofuels are currently in development with early versions in use (RSB, 2010). The principles on which these are based – attention to law, stakeholder participation, climate change mitigation, human, labor and land rights, rural and social development, food security, waste management, resource conservation and environmental protection – apply equally well to agricultural production systems for biobased products as they do for bioenergy, a point reinforced by the recent name change of one of the principle cooperative initiatives in international standardization to broaden from biofuels to biomaterials and biomass production, more generally (RSB, 2013). Local standards may in some cases exceed international standards but will need close coordination to avoid conflicts with international agreements and rules such as those of the World Trade Organization. The complex issues now being researched and addressed in

sustainable industrial feedstock production should provide new perspectives on the improved sustainability of agriculture overall.

Glossary

Customer order decoupling point (CODP) A CODP is an inventory point in the company's value chain where products are linked to specific customer orders. After the CODP raw materials, half-fabricates, or end-products are processed and delivered to start fulfilment of customer orders.

Food logistics management Concerns the planning, implementation, and control of the supply, storage, and distribution of food products and related information from the point-of-origin to the point-of-consumption in order to meet customer requirements.

Food quality standards Concerns requirements on integrated sets of food quality and safety attributes, designed by retailers, large food industries, or other supply chain stakeholders (e.g., NGOs), to which supply chain parties have to comply to achieve a 'license to operate and deliver.'

Logistics network A network of interdependent organisations who jointly manage the flow of materials and information from suppliers to end users.

Supply chain A supply chain consists of all parties, from primary producers to final consumers, involved in fulfilling customer demands.

Traceability The ability to determine the on-going location of products and to trace products back to their origin and used production methods.

Virtualization Virtualization in a supply chain context is the digital representation of physical or imaginary products and resources, which allows for the decoupling of physical flows and information aspects of supply chain operations.

Introduction

Since the 1980s, management literature stresses the need for collaboration among successive actors in the (global) supply chain, from primary producers to final consumers, to better satisfy consumer demand at lower costs (Lambert *et al.*, 1998; van der Vorst, 2000). This new way of managing the business within each link and the relationships with other members of the supply chain has been named supply chain management (SCM). A driving force behind SCM is the recognition that suboptimization occurs if each organization in a supply chain attempts to optimize its own results rather than to coordinate its goals and activities with other organizations to optimize the results of the chain (Cooper *et al.*, 1997). This holds true especially in food supply chains because of shelf-life constraints of food products and increased consumer attention for safe and environment/animal-friendly production methods (van der Vorst *et al.*, 2005).

The increased interest in SCM has been spurred by intensified global competition, demographic and market developments (such as product proliferation and shorter product life cycles) combined with developments in information and communication technology (ICT) that enable more efficient execution of processes and more frequent exchange of huge amounts of information for coordination purposes and to provide transparency of production and distribution processes for the food supply chain's stakeholders. These stakeholders, in Western markets as well as in emerging economies, have become more demanding and place new demands on attributes of food such as safety, quality (guarantees), diversity, and associated information (Jacxsens *et al.*, 2010). **Table 1** depicts some of the main developments in demand and supply in (global) food supply chains.

These developments put dynamic requirements on the performance of the food system initiating a reorientation of companies in agriculture and food industry on their roles, activities, and strategies (van der Vorst *et al.*, 2005). Demand and supply are no longer restricted to nations or regions but have become international processes. An increasing concentration has been seen in agribusiness sectors, an enormous increase in cross-border flows of livestock and food products, and the creation of international forms of cooperation. The food industry has become an interconnected system with a large variety of complex relationships, reflected in the market place by the formation of (virtual) food supply chains via alliances, horizontal and vertical cooperation. The latter encompass the development and implementation of enhanced quality, logistics, and information systems. To satisfy the increasing demands of consumers, governments, business partners, Non Governmental Organisations (NGOs) and to obtain the 'license to produce and deliver,' companies continuously have to work on innovations in products, processes, and forms of cooperation in food supply chains.

This article focuses on the concepts and main developments in logistics, quality management, and transparency in food supply chains. An overview of these developments will be given and the impact on the design and management of the food supply chain network (FSCN) will be discussed. Practical examples will be presented in boxes to exemplify and clarify theoretical concepts.

Global Supply Chain Management and Logistics (Parts of this Section are Based on van der Vorst *et al.* (2005))

Food Supply Chain Management

The term 'SCM' is relatively new. It first appeared in logistics literature in 1982 as an inventory management approach with

Table 1 Overview of generic developments at the demand and supply side

Demand side	*Supply side*
• Higher quality, safety, and convenience products	• International geographical transitions
• More value-added products (ready to eat)	• Bigger firms (concentration) and specialization
• Increasing product variety	• Outsourcing; focus on core competences
• Shorter product life cycle	• More cooperation in (dynamic) supply chain networks
• Healthy and ecological	• Focus on added value and sustainability
• More powerful well-informed customers	• Branding strategy, search for consumer contact
• Bigger retail firms (concentration)	• Search for new distribution channels
• 24×7 Retail services	• More use of new technologies
• Battle between private and brand label	• New entrants in the network
• New types of stores; market differentiation	

Source: Adapted from van der Vorst, J.G.A.J., Da Silva, C., Trienekens, J.H., 2007. Agro-industrial supply chain management: Concepts and applications. FAO Agricultural Management, Marketing and Finance, Occasional Paper 17, 56 p. Rome: FAO.

an emphasis on the supply of raw materials (Oliver and Webber, 1982). Logistics managers in retail, grocery, and other high inventory industries began to see that a significant competitive advantage could be derived through the management of materials through inbound and outbound channels. Purchasing literature states that SCM evolved from an upgrade of the purchasing function to an integral part of the corporate planning process. Since its introduction in the retail industry, the supply chain concept has spread to other industries such as computers and copiers.

Around 1990, academics first described SCM from a theoretical standpoint to clarify how it differed from more traditional approaches to managing the flow of materials and the associated flow of information (Cooper and Ellram, 1993). SCM can be defined as follows (based on van der Vorst, 2000):

SCM is the integrated planning, coordination, and control of all business processes and activities in the supply chain to deliver superior consumer value at less cost to the supply chain as a whole while satisfying the variable requirements of other stakeholders in the supply chain (e.g., government and NGOs).

The ultimate aim of a supply chain is to deliver value for customers. Value is first of all the amount consumers are willing to pay for what a company provides and it is measured by total revenue. The concept 'value-added activity' originates from Porter's 'value chain' framework and characterizes the value created by an activity in relation to the cost of executing it (Porter, 1985). Currently, the value concept is more expanded. Here values associated with the so-called 'Triple Bottom Line' or 'Triple P': People, Planet, and Profit (FAO, 2012) are dealt with. So next to the financial performance, the social and environmental performances are also incorporated (Baldwin, 2009). These latter two lead to (qualitative) attributes that are generally spoken associated with the product itself (biologically produced), the companies producing it (social policy), and the raw materials (genetically modified organisms?) and resources (child labor?) used.

Figure 1 depicts a generic supply chain at the organization level within the context of a complete supply chain network. Each firm is positioned in a network layer and belongs to at least one supply chain: that is, it usually has multiple (varying) suppliers and customers at the same time and over time. Other actors in the network influence the performance of the chain. Therefore, the analysis of a supply chain should preferably take place or be evaluated within the context of the complex network of food chains, in other words a FSCN.

In promoting and building a strong supply chain, organizations need to understand the way competition is changing. Competitiveness currently depends on being able to join supply chains, and effective participation in, and control of, global food chains. To be competitive, coordination and sharing of information need to be undertaken between network partners. The result of the supply chain is measurable via the acceptance of the end product by the consumer. Nowadays, as discussed, this acceptance is a combination of availability, price, quality and food safety and other quality attributes. The highest added value for all participants can only be achieved when these aspects are optimized at the chain or network level. This is especially true for realizing a high quality and safe product. Food safety and high quality products are not the sole responsibility of an individual organization, but of the entire food chain. As the different actors in the supply chain each have their own role in ensuring the quality and safety of the end product, their activities should be closely coordinated. This should and can be facilitated by efficient logistics systems and exchanging information between chain/network participants. Note that FSCN have a number of specific characteristics that impact the design and management of these systems, depicted in **Table 2**.

The authors look at the operational processes that make use of inventory, transportation, facilities, and information. The traditional view on logistics management in a supply chain is the cycle view. A cycle view of the supply chain clearly defines the business processes and activities involved and the owners of each process (hence roles and responsibilities). Furthermore, because of the inventory being held between the cycles, the main processes are decoupled to a certain extent. This implies that each process can function independently and is not hindered by 'problems' in other processes. This opposes the just-in-time philosophy, which states, among other things, that the decoupling of activities by inventories should be eliminated as it hinders supply chain visibility and supports the suboptimization of the supply chain.

Owing to increasing consumer demand variability and uncertainty resulting in an increased demand for capacity–flexibility

(and thus reduction of inventories), the push/pull view on supply chains has gained more interest (Figure 2). This view focuses on the extent to which customer orders penetrate or may penetrate the logistic system. The customer order decoupling point (CODP) – also called order penetration point (Olhager, 2003) – separates the part of the organization whose management decisions are governed by customer orders (pull process) from the part of the organization where production plans are made based on forecasted demand of consumers or forecasted orders from partners downstream in the chain (push process). Downstream of the CODP the material flow is directly controlled by customer orders and the focus is on customer responsiveness (lead time and flexibility). Upstream toward suppliers, the material flow is controlled by forecasting and planning, and the focus is on efficiency (usually employing large batch sizes) and taking into account inherent properties of material flows and production capacities and resources. It must be determined where the decoupling point should be for each product–market combination or product group in the company. Therefore, a company can have multiple CODPs at different locations and even a single product can have more than one, as it can serve multiple product–market combinations.

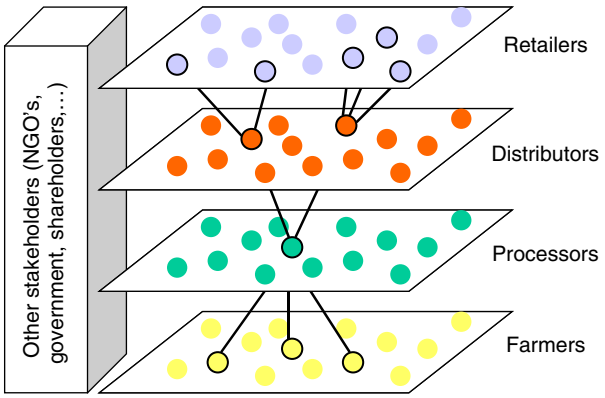

Figure 1 Schematic diagram of a supply chain from the perspective of the processor (bold flows) within the total supply chain network. Adapted from Lazzarini, S.G., Chaddad, F.R., Cook, M.L., 2001. Integrating supply chain and network analyses, the study of netchains. Journal on Chain and Network Science 1, 7–22.

The CODP and postponement concepts result in logistics structures in which a consolidation point is used to perform product differentiation to customer demands; the supply part toward the consolidation point is efficiency oriented and the distribution part aims for responsiveness. Hoekstra and Romme (1992) distinguish five possible positions of a decoupling point (DP). When these positions are translated to the example of the fresh produce sector (flowers, vegetables, fruits, etc.), four chain designs come to the front (see Figure 3). In the first two designs all products are delivered to the customers from local or regional stock – no customization activities are performed. In design 3, products are customized (that is value-adding activities to make the product customer specific are performed) at the auction, trader or hub and successively delivered to the market outlets. Finally, in design 4

Table 2 Overview of main characteristics of food supply chains and their impact on management of these chains

SC stage	*Product and process characteristics*	*Impact on management*
Overall	• Shelf-life constraints for raw materials, intermediates, and finished products and changes in product quality level while progressing the supply chain (decay) • Recycling of materials required	• Timing constraints • Information requirements • Return flows
Growers/ producers	• Long production throughput times (producing new or additional products takes a lot of time) • Seasonality in production • Variability of quality and quantity of supply	• Responsiveness • Flexibility in process and planning
Food industry	• High volume and low variety (although the variety is increasing) production systems • Highly sophisticated capital-intensive machinery focusing on capacity utilization • Variable process yield in quantity and quality due to biological variations, seasonality, random factors connected with weather, pests, other biological hazards • A possible necessity to wait for the results of quality tests (quarantine) • Alternative installations, alternative recipes, product-dependent cleaning and processing times, carryover of raw materials between successive product lots, etc. • Storage buffer capacity is restricted, when material, intermediates or finished products can only be kept in special tanks or containers • Necessity to value all parts because of complementarity of agricultural inputs (e.g., beef cannot be produced without the coproduct hides) • Necessity for lot traceability of work in process due to quality and environmental requirements and product responsibility	• Importance of production planning and scheduling focusing on high capacity utilization • Flexibility of recipes • Timing constraints, information and communication technology-possibility to confine products • Flexible production planning that can handle this complexity • Need for configurations that facilitate tracking and tracing
Auctions/ wholesalers/ retailers	• Variability of quality and quantity of supply of farm-based inputs • Seasonal supply of products requires global (year-round) sourcing • Requirements for conditioned transportation and storage means	• Pricing issues • Timing constraints • Need for conditioning • Preinformation on quality status of products

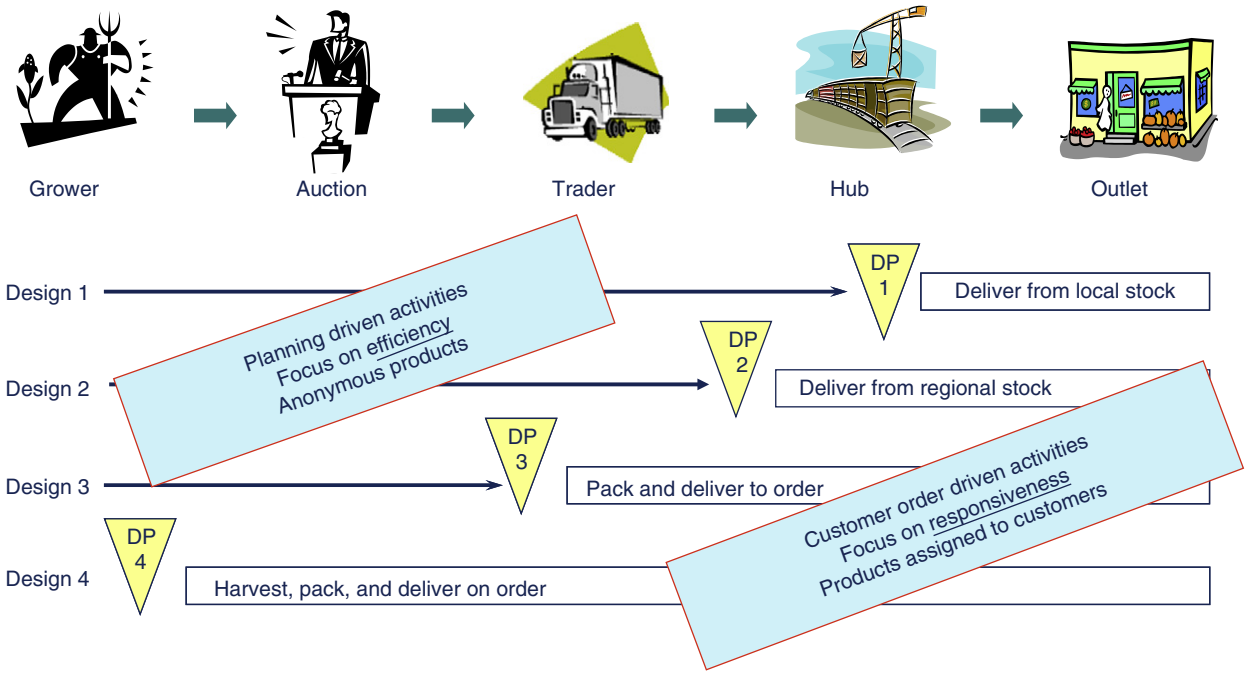

Figure 3 Four network designs with different decoupling points (reversed triangle refers to inventory that acts as a decoupling point). Reproduced from van der Vorst, J.G.A.J., Duineveld, M., Scheer, F.P., 2006. Logistics orchestration in the ornamental plant supply chain network: Towards responsive and differentiated demand driven networks. FloriLog-regie Position Paper, 46 pp. Zoetermeer: Transforum Agro & Groen.

the grower has a direct relationship with the final customer and harvest, packs and delivers its products (via traders or transporters) to customer outlets. The auction is bypassed in this network design.

There are many factors exerting an upstream or downstream influence on the position of the CODP. It is a balancing process between (Olhager, 2003):

1. Market-related factors, such as the delivery lead time requirements set by the market, product demand uncertainty, product range, and product customization requirements;
2. Product-related factors, such as possibilities for modular product design and product customization opportunities; and
3. Production- and distribution-related factors, such as the production and distribution lead time and the flexibility of the production and delivery process.

All these factors indicate to what extent it is possible or reasonable to harvest or pack products to order; for example, the more unpredictable the demand, the more responsive the supply chain should be; and if long delivery lead times are

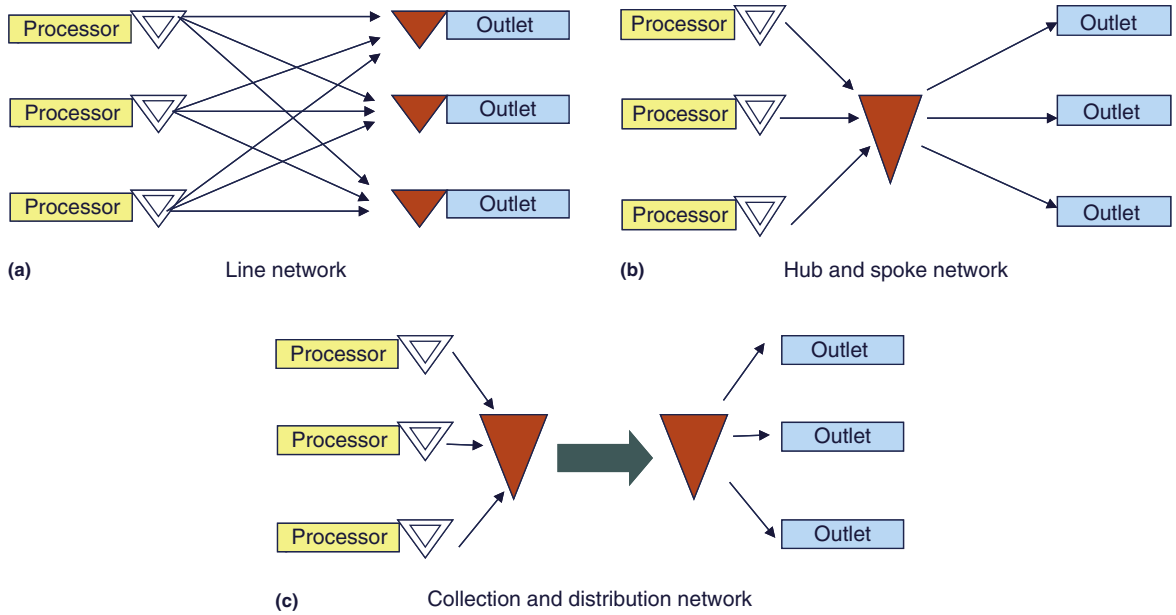

Figure 4 Overview of the three main network designs (reverse triangle = stock point).

accepted by customers, the more efficient the supply chain can be organized.

The last decade, the general trend is to shift the CODP upstream the supply chain (toward suppliers) in order to increase the responsiveness to variable market demand and limit the amount of nonvalue-adding activities. Information is then required to increase the speed of information exchange as to realize acceptable lead times. A good example is the fabrication of cars; nowadays cars are assembled only after the customer order has been received requiring very flexible manufacturing systems. However, if short lead times are requested and distances are large it is evident that one needs a stock point close to the market.

Logistics Network Design

A lot of research has been conducted on the design of distribution networks (including inventory location) and the added value of consolidation practices. Key decisions are where to store goods, where to (re)pack goods, and how to transport goods to customers.

Consolidated distribution is required when the volume of the goods to be distributed is smaller than the transport unit size (combining less than truck loads) or when the total traveling distance can be reduced by recombining full truck loads. Consolidation is often needed when, for example, the delivery frequency is increased with a resulting decrease in delivery batch size. There are three types of consolidated transportation (Ghiani *et al.*, 2004):

- Temporal consolidation, this means that goods from trucks that have different departing times are consolidated into other transport units (shifting with schedules in time);
- Facility consolidation, this means that goods that have different destinations are now transported together in a transport unit for (part of) the route; and
- Product consolidation, this means that goods with different characteristics (e.g., chilled, frozen or potted plants and vegetables) are transported together in one transport unit.

The result of consolidation should be a reduced total number of transport unit kilometers (and thus environmental pollution) by either a reduced transport distance (by optimal route planning) or reduced number of freights movements (by more full transport unit loads). Consolidated distribution is therefore a specific network design of sources (departing points), routes and sinks (destinations).

In general, one can state that there are three basic distribution network designs (see Figure 4):

- Line network, where each distributor has its own transport network to outlets.
- Hub and spoke network, where each distributor delivers the goods to a central hub where goods are exchanged aiming for specific network destinations.
- Collection and distribution network, especially suited for international networks, where each distributor delivers the goods to a central collection hub; goods are consolidated in time, regional destination, and product type; and successively transported to a distribution hub, where goods are resorted (added with products from other sources) and distributed to specific locations.

Note that inventory management is one of the design variables in the distribution network. In Figure 3(a) a number of inventory points are presented; however, these could just as well be cross-dock facilities where consolidation activities are performed and no inventory is kept.

As can be seen from Figure 4(a) hub may perform a consolidation or concentration function to combine many small separate flows into larger flows or split a larger flow into separate smaller flows for different destinations. Thus, hubs are intermediate points along the paths followed by

Box 1 Consolidation of distribution

In 2012 in the Netherlands, four producers of fast moving consumer goods (namely HJ Heinz, FrieslandCampina, Hero Benelux, and SCA Hygiene Products) started a collaboration to consolidate the distribution of their goods flows to (the same) retail distribution centers. They jointly selected a logistics service provider (Nabuurs) who established a new joint distribution center that stores products from all four producers. Distribution now takes place from three locations with a total surface of 63 000 m^2 (90 000 pallet locations). With this process they have changed from a line network, in which each partner delivered the retailers independently, to a hub and spoke network, in which all products are delivered to and from a central warehouse. Research is taken place to assess the possibility of setting up a joint distribution center in the international market as well, from which the products would be distributed to the international clients. This would then further transform their network into a collection and distribution network. The same research activities (and transition processes) are taken place in the flower trade network (see www.davinc3i.com).

origin–destination flows. Groothedde (2005) provides an excellent literature review on hub network design.

It is clear that the network complexity greatly influences the opportunities for improved logistics network designs and roles of logistics orchestrators. The next section will discuss the ins and outs of logistics orchestration concepts (**Box 1**).

Logistics Orchestration

'Orchestrate,' by Webster dictionary definitions, refers to 'the act of arranging or combining so as to achieve a desired or maximum effect.' Orchestration, translated to global food supply chains, means coordination of these chains so as to achieve maximum customer value. Owing to the high complexity and multitude of actors and stakeholders in global food supply chains, logistics orchestration is in many cases performed by third party logistics service providers (LSP).

Logistics outsourcing means an organization uses an LSP to carry out an activity, which is originally performed in-house (Bolumole, 2001). The role of LSPs has changed since the emergence of the SCM concept. SCM asserts that organizations along the supply chain need to reconfigure their operations by internal and external cooperation in order to accommodate changing customer requirements. To achieve seamless supply chain operations, organizations are looking for solutions from LSPs (van der Vorst *et al.*, 2006).

There are different ways to distinguish LSPs, for example, according to their degree of customization (Delfmann *et al.*, 2002), or by ability of general problem solving and customer adaptation (Hertz and Afredsson, 2003). On the basis of these researches, three main types of LSPs (Hsiao *et al.*, 2010) can be distinguished:

1. Standard LSPs (second party logistics): The companies who provide standard and traditional services, such as transportation and warehouse-based (Long, 2003). The service fulfilled for the customers are standardized, resulting in highly interchangeable services among this type of LSPs. These companies are highly specialized in their field and do not take over coordination or administrative functions for their customers. Standard LSPs plan, implement, and control their own logistics system according to their requirements and considerations.
2. Integrated LSPs (third party logistics; 3PL): These companies provide value-adding services and also provide at least two standard services without becoming the owner of the goods. In other words, they combine selected standard services to bundles of logistics services according to their customers' wishes. The operational coordination and arrangement of these services bundles are provided by the LSP, whereas the disposition lies in the responsibility of the buying company (Delfmann *et al.*, 2002). For example, transportation combined with value-adding activities such as assembly, repacking and quality control activities. These bundles are offered undifferentiated for all potential customers and thus cannot be regarded as customized services.
3. Logistics network orchestrator (fourth party logistics; 4PL): The term 4PL was first coined and registered by Accenture Consulting Company as a trademark in 1996. Accenture defined that "A 4PL provider is a supply chain integrator that assembles and manages the resources, capabilities, and technology of its own organization with those of complementary service providers to deliver a comprehensive supply chain solution." (Hertz and Afredsson, 2003). A network orchestrator is a nonasset-based service provider, which means that it has no trucks or warehouses of its own, who outsources logistics activities to standard or integrated LSPs. It is a company who provides supply chain planning activities and designs logistics services and logistics systems according to the preferences of their clients. Overall, a network orchestrator takes over coordinative and administrative responsibility for their customers, and takes over responsibility for the effectiveness and efficiency of the logistics system of its customer (Delfmann *et al.*, 2002).

Koppius and Eric (2005; 274) state that "A network orchestrator has an overview of the resources and capabilities of the network members on one hand and the demands of the end-customer on the other hand. The network orchestrator is responsible for configuring the network such that customers and network member preferences are satisfied." A network orchestrator assembles and manages the resources, capabilities, and technology of its own organization, clients, with those of complementary service providers. Collaborators together carefully plan how capacity should be created throughout the system, and decide jointly where and in what quantities inventories of various types should exist (Stadtler, 2005). Moreover, they must also decide in advance what actions will be taken when various unplanned events occur. Thus strategic and tactical plans must be created collaboratively to achieve the maximum system effectiveness. These plans describe how the supply chain will respond to variations and uncertainty (Muckstadt *et al.*, 2001). Activities that are executed by a 4PL are all related to the obtaining of the right information, and translate this into activities. Examples of activities executed by a 4PL are: market search, logistic network management, transport sourcing, optimization, administration, carrier contract negotiation, order handling and invoice management, production,

warehousing and distribution, returns management, and analyzing and reporting of key performance indicators (performance management).

Several researches are done about the reasons for the increasing use of 3PLs in the supply chain. Shanahan (2004) surveys in his article '3PL Roles Continue to Grow,' the growing role of logistic providers as integral part in the global supply chain and the arguments behind this. According to Bolumole and Wilding, the main reasons why organizations decide to make use of 3PLs are:

- To deal with a more complex supply chain;
- Increasing focus on core business processes;
- Reduction of distribution costs;
- Avoiding extra (inefficient) investments;
- To get access to more centralized distribution systems, what many companies do not have;
